Between data cleaning and inference: Pre-averaging and robust estimators of the efficient price

Per A. Mykland,*, Lan Zhang

A B S T R A C T

Pre-averaging is a popular strategy for mitigating microstructure in high frequency financial data. As the term suggests, transaction or quote data are averaged over short time periods ranging from 30 s to five min, and the resulting averages approximate the efficient price process much better than the raw data. Apart from reducing the size of the microstructure, the methodology also helps synchronise data from different securities. The procedure is robust to short term dependence in the noise.

Since averages can be subject to outliers, and since they can pulverise jumps, we have developed a broader theory which also applies to cases where M-estimation is used to pin down the efficient price in local neighbourhoods. M-estimation serves the same function as averaging, but we shall see that it is safer. Good choices of M-estimating function greatly enhance the identification of jumps. The methodology applies off-the-shelf to any high frequency econometric problem.

In this paper, we develop a general theory for pre-averaging and M-estimation based inference. We show that, up to a contiguity adjustment, the estimated process behaves as if one sampled from a semimartingale (with unchanged volatility) plus an independent error.

Estimating the efficient price is a form of pre-processing of the data, and hence the methods in this paper also serve the purpose of data cleaning.

1. “A tale full of sound and fury”

The recent literature on high frequency financial data has indeed been focused on sound (noise) and fury (jumps). While the tale is significant and important, one of the lessons from it is that both noise and jumps can severely impact statistical significance. Especially when they occur in combination. ①

① See, in particular, the discussions in Jacod and Protter (2012, Chapter 16.5, pp. 521-563) and Aït-Sahalia and Jacod (2014, Appendix A.4, p. 496-502).
Unlike Shakespeare’s Macbeth, we are fortunately not here faced with ultimate questions, but rather with the more prosaic one of finding a signal – something significant – in the middle of the sound and fury. The purpose of this paper is to introduce two (intertwined) approaches which we believe can be helpful: M-estimation, and contiguity.

The analysis of these data started with the work of Andersen and Bollerslev (1998a,b), Andersen et al. (2001, 2003), Barndorff-Nielsen and Shephard (2001, 2002), Barndorff-Nielsen (2004), Jacob and Protter (1998), Zhang (2001) and Mykland and Zhang (2006), and the group at Olsen and Associates (Dacorogna et al. (2001)), focusing on the concept of realised volatility (RV). The work was based on the assumption that log prices follow a semimartingale of the form

\[ dX_t = \mu_t dt + \sigma_t dW_t + dJ_t, \]

(1)

where \( J_t \) is a process of jumps. \( W_t \) is Brownian motion; \( \mu_t \) and \( \sigma_t \) are random processes that can be dependent with \( W \). We also denote the continuous part of \( X_t \) by

\[ dX^c_t = \mu_t dt + \sigma_t dW_t. \]

(2)

The semimartingale model for prices is required by the no-arbitrage principle in finance theory (Delbaen and Schachermayer, 1994, 1995, 1998).

Somewhat startlingly, the data had feedback to the theory: log prices are not semimartingales after all. The authors found that in actual data, the RV does not, in fact, converge as predicted by theory. This was clarified by the so-called signature plot (introduced by Andersen et al. (2000), see also the discussion in Mykland and Zhang (2005)). This led researchers to investigate a model where the efficient log price \( X_t \) is latent, and one actually observes a contaminated process \( Y_t \):

\[ Y_t = X_t + \epsilon_t, \]

(3)

The distortion \( \epsilon_t \) is called either “microstructure noise” or “measurement error”, depending on one’s academic field (O’Hara, 1995; Hasbrouck, 1996). The \( t \) can be transaction times, or quote times.

The discovery of the impact of microstructure on inference led researchers to seek methods for high frequency data which allow for such noise. So far, five main approaches have come to light:

- Two- and Multi-scale estimation: weighted subsampled RVs (Zhang et al., 2005; Zhang, 2006, 2011)
- Realised Kernel: weighted autocovariances (Barndorff-Nielsen et al., 2008)
- Pre-averaging: take weighted local averages before taking squares (Jacob et al., 2009a; Podolskij and Vetter, 2009b)
- Quasi-likelihood (Xiu, 2010)
- The local method of moments of Bibinger et al. (2014).

All methods can achieve up to \( O_p(n^{-1/4}) \) convergence rate for volatility, which is as good as for parametric inference (\( \sigma, \mu \) constant), cf. Gloter (2000), Gloter and Jacob (2000, 2001). The approaches mainly differ in treatment of edge effects. (See Mykland and Zhang, 2014 for a systematic discussion of edge effects.) Studies based on different microstructure models are also in development (Robert and Rosenbaum, 2009). A recent, more abstract, line of enquiry is based on equivalence of experiments (Hoffmann, 2008; Reiss, 2011; Jacob and Reiss, 2014; Bibinger et al., 2014). The latter path is related to our own; see Example 3 in Section 3.1.1.

However, existing literature has been confined to estimation of volatility and very closely related objects. Also each estimator has been studied on a case by case basis. This is in contrast to the much greater generality which can be achieved when there is no microstructure, including high frequency regression, analysis of variance, powers of volatility (Mykland and Zhang, 2006, 2009; Kalnina, 2012; Jacob and Rosenbaum, 2013), empirically based trading strategies (Zhang, 2012), semivariances (Barndorff-Nielsen et al., 2009b), resampling (Kalnina and Linton, 2007; Gonçalves and Meddahi, 2009; Kalnina, 2011; Gonçalves et al., 2013), volatility risk premia (Bollerslev et al., 2011, 2009), the volatility of volatility (Vetter, 2011), robust approaches to volatility, jump detection and estimation, and so on. In other words, the research assuming no microstructure has flourished. To some extent, this is legitimate. As an old saying puts it, one has to learn to walk before one learns how to run. Also, there is the hope that either subsampling or pre-averaging can be used to eliminate the microstructure problem, and/or that data can be cleaned so hard that they do not have error any more. Even with this latter strategy, however, it is difficult to assess the impact of microstructure noise without including it in the model. Data processing, such as subsampling or pre-averaging, may also distort the jump characteristics of the data, and thus adversely affect subsequent inference.

This raises the question of whether we as a community will have to redo everything on an estimator-by-estimator basis for more realistic models that allow for microstructure noise and/or jumps.

The purpose of this paper is to find a way around this gargantuan task. We characterise the price process with sound and fury in presence. We develop a general theory that asymptotically separates the impact of the continuous evolution of a signal (i.e. latent efficient price), of the jumps, and of the microstructure. The theory covers both pre-averaging and M-estimation. On the one hand, our theory reduces the impact of microstructure, irrespective of the target of estimation. Our approach will not solve all problems for going between the noise and no-noise cases, but it is a step in the direction of typing these two together. On the other hand, our theory does not truncate jumps before analysis, and we show that we can tightly control the degree of modification of jumps when using a suitable M-estimator preprocessing before analysis. Thus the inference is transparent about how jump characteristics play a role in inference, again regardless of the “parameters”.

We have two main clusters of results. One is Theorems 1–4 in Section 2.5, which show that by moving from pre-averaging to pre-M-estimation, one can to a great extent avoid the pulverisation of

\[ 2 \text{ An instantaneous version of RV was earlier proposed by Foster and Nelson (1996) and Comte and Renault (1998). Antecedents can be found in Rosenberg (1972), French et al. (1987) and Merton (1980). For a number of other early papers, see the anthology (Shephard, 2005). For further references, see the review by Shephard and Andersen (2009).}

\[ 3 \text{ Some of the cited papers allow for jumps, others not.}

\[ 4 \text{ Realised kernel and Multi-scale estimation can be given adjustments to be asymptotically equivalent, see Bibinger and Mykland (2016).}

\[ 5 \text{ Other earlier methods based on parametric assumptions include, in particular, (Zhou, 1998; Curci and Corsi, 2005), which uses the famous parameter-free diagonalisation of the covariance matrix.}

\[ 6 \text{ Specifically Bi- and Multipower Variation (Podolskij and Vetter, 2009a; Jacob et al., 2009b) and integrated covariance under asynchronicity (Zhang, 2011; Barndorff-Nielsen et al., 2009a; Christensen et al., 2008a). The only other main classes of estimators that have been studied in the presence of noise are jump (see Footnote 8) and leverage effect (Wang and Mykland, 2014; Alt-Sahalia et al., 2013).}

\[ 7 \text{ In addition to the other papers cited, see, e.g., Andersen et al. (2012, 2014), Barndorff-Nielsen and Shephard (2001), French et al. (1987) and Merton (1980). For a number of other early papers, see the anthology (Shephard, 2005). For further references, see the review by Shephard and Andersen (2009).}

jumps that is present in pre-averaging. M-estimation also opens the possibility for better efficiency (Section 2.5.4). The other main result is the Contiguity Theorem 11 in Section 4, which shows that, under pre-averaging (including pre-M-estimation), one can behave as if there is no pre-processing at all, but that there will appear to be extra micro-structure. This is up to contiguity, which can be corrected for post-asymptotically.

In the next section, we outline the ingredients of our theory in local neighbourhoods. Then in Section 3 we show how local behaviour in neighbourhoods can be converted into a global behaviour using Edgeworth expansions and contiguity. Section 4 then contains our main contiguity results. Examples of application are given in Section 5, whereupon we conclude the paper. Proofs are in the Appendices.

2. The elements of a general theory: local behaviour

2.1. Background and some notation

Our general theory will be based on estimating the efficient price $X$ in small neighbourhoods. Specifically, we assume that observations $Y_{n,i}$ of the form (1)–(3) are made at times

$$0 = t_{n,0} < \cdots < t_{n,i} < \cdots < t_{n,n} = T. \quad (4)$$

The index $n$ represents the total number of observations, and our arguments will be based on asymptotics as $n \to \infty$ while $T$ is fixed. Meanwhile, $K_n$ neighbourhoods or blocks are defined by a much coarser grid of $\tau_{n,i}, i = 1, \ldots, K_n$, also spanning $[0, T)$, so that block # $i = \{t_{nj} : t_{n,i-1} \leq t_{nj} < t_{n,i}\}$

$$\text{(the last block, however, includes } T; \tau_{n,K_n} = T). \text{ We then seek an estimate } \hat{X}_{n,i} \text{ of the efficient price } X \text{ in the time period } [\tau_{n,i-1}, \tau_{n,i}).$$

By “local behaviour” we mean the behaviour of a single $X_{n,i}$ in a single time period $[\tau_{n,i-1}, \tau_{n,i})$. We show in the later Sections 3–4 how to sew together the local behaviours across all the time periods.

If we define the block size by

$$M_{n,i} = \# \{j : t_{n,i-1} \leq t_{nj} < t_{n,i}\}, \quad (6)$$

the hope is that substantial precision in the estimation of $X$ is obtained if $M_{n,i} \to \infty$ with $n$, but with $M_{n,i}$ increasing sufficiently slowly that the actual time interval $[\tau_{n,i-1}, \tau_{n,i})$ stays small. After all, the efficient price $X$ is a moving target.

**Notation 1.** When there is no room for confusion about the number observations, we occasionally suppress the first subscript $n$, and write $t_{i,j}$ instead of $t_{n,i,j}$, $\tau_{i,j}$ instead of $\tau_{n,i,j}$, $M_{i,j}$ instead of $M_{n,i,j}$, and so on.

**Example 1** (Pre-averaging). This idea is behind the concept of pre-averaging (Jacob et al., 2009a; Podolskij and Vetter, 2009a,b; Jacob et al., 2009b). Define block averages for block $i, [\tau_{i-1}, \tau_i]$

$$\hat{Y}_i = \frac{1}{M_{i}} \sum_{n-1 \leq j \leq n} Y_{j,i},$$

and let $\bar{X}_i$ be defined similarly based on $X$. The averaging yields a reduction of the size of microstructure noise from $O_p(1)$ to $O_p(M_{i}^{-1/2})$, since, by central limit type considerations,

$$\hat{Y}_i = \bar{X}_i + \bar{e}_i.$$
solution of the estimating equation \( \sum_{j=1}^{\ell} \psi(Y_j - \hat{\theta}_m) = 0 \). Here, the estimating function \( \psi \) is an anti-symmetric \( \psi(-x) = -\psi(x) \) and usually nondecreasing function. \( \psi \) is usually bounded, but does not have to be. It is assumed that the noise satisfies \( E \psi(x) = 0 \) (more about this in Condition 3). If the \( \epsilon_j \) are iid: \( M^{1/2}(\hat{\theta}_m - \theta) \xrightarrow{d} N(0, \sigma^2) \) where, subject to \( E \psi(x)^2 < \infty \),
\[
\sigma^2 = \frac{\text{Var}(\psi(x))}{(E\psi'(\epsilon))^2}.
\] (8)
If the iid assumption is weakened to stationarity and exponential strong mixing, with exponential decay of the mixing coefficients (see, e.g., Hall and Heyde, 1980, p. 132 for discussion of mixing concepts) then the theory goes through with \( \sigma^2 = \frac{\text{Var}(\psi(x)) + 2 \sum_{j=1}^{\infty} \text{Cov}(\psi(x), \psi(x+j)) / (E\psi'(\epsilon))^2} \). The theory presented in this paper is conjectured to also remain valid when the microstructure noise is similarly stationary and strong mixing.

- For bounded \( \psi \), estimation is robust to outliers by truncation: asymptotic variance is minimax in a certain set of distributions for \( \epsilon \). It also has desirable “breakdown properties” (see the references in the previous section).

2.4. Location of the efficient price: definition and conditions

In analogy with the classical theory, we define the estimated process \( \hat{X}_i \) in block \( [\tau_{i-1}, \tau_i) \), \( \hat{X}_i \) is given by
\[
\sum_{\tau_{i-1} \leq \tau < \tau_i} \psi(Y_i - \hat{X}_i) = 0.
\] (9)

The “classical” forms of \( \psi \) are given as

1. For \( \psi(x) = x \), (9) yields pre-averaging: \( \hat{X}_i = \bar{Y}_i \);
2. For \( \psi(x) = \text{sign}(x) \), (9) yields pre-medianisation: \( \hat{X}_i = \text{median}(Y_i) \) in block \( i \). In the case of an even number of observations, we define the median as the mean of the two middle order statistics;
3. An intermediate solution, the typical M-estimator form Huber (1981), lets \( c \) a positive constant and sets \( \psi \) to be
\[
\psi_c(x) = \begin{cases} 
  x & \text{for } |x| \leq c \\
  c \times \text{sign}(x) & \text{otherwise}.
\end{cases}
\] (10)

This form represents a compromise: it behaves like the mean for small observations, and like the median for large observations. We shall see that for \( \hat{X}_i \), it means treating the jumps and the microstructure robustly, while averaging the part of the returns that come from the continuous \( X^t \). The estimating function \( \psi_c \) can be smoothed around \( \pm c \) if desirable.

We shall use two sets of conditions on \( \psi \). The first order representation theorems in Section 2.5 have weak conditions on \( \psi \). For higher order representation theorems, and for the global (contiguity) results in Section 4, we need to make slightly more restrictive assumptions than what is common in the iid setting, as follows.

Condition 1A. \( x \rightarrow \psi(x) \) is nondecreasing in \( x \).

Condition 1B (For Results Involving Second Order Asymptotics or Contiguity). In addition, the \( M \)-estimating function \( \psi \) is anti-symmetric \( \psi(-x) = -\psi(x) \), strictly increasing in a neighbourhood of \( x = 0 \), with a bounded and continuous derivative \( \psi' \) which is absolutely continuous. Also, \( \psi' \) is bounded.

Unfortunately, Condition 1B does not cover the median. As the median will turn out to be an interesting special case, we believe the contiguity properties of the median deserves a separate paper.

As a warmup, we here show how \( \hat{X}_i \) relates to the classical M-estimator. We make assumptions here that are stronger than what is used in this section, but will be needed in later sections.

Condition 2 (The Process). The observables \( Y_i \) are given by (1)–(3). The \( M \) process is a semimartingale, and \( \mu_t \) and \( \sigma_t \) are random processes; \( \mu_t \) is locally bounded, and \( \sigma_t \) is a continuous semimartingale. \( (J_{t_{0},t_{0}+T}) \) is a process of finitely many jumps, which is independent of the continuous part \( X^t \) of \( X \).\(^{10}\) We assume that the \( M \) process and all its components (such as \( \sigma_t, \mu_t, W_t \), and \( J_t \)) are adapted to a filtration \( \mathcal{F}_t \).\(^{10}\)

Condition 3 (The Microstructure). We assume that the \( \epsilon_j \) are i.i.d.

Also assume that \( x \rightarrow E \psi(x) \) is finite and continuous in \( x \) for all \( x \in \mathbb{R} \). Also, we suppose that the function \( x \rightarrow E \psi(x) \) is continuously differentiable and strictly increasing in \( x \). We further suppose that \( E \psi(x) = 0 \), but this latter assumption is only required in the asymptotic properties of \( \hat{X}_i \).

The \( \epsilon_j \) are assumed to be independent of \( \mathcal{F}_t \) (in particular, of the \( X \) process) and of the observation times.

Condition 4 (The Observation Times). The observation times \( J \) are independent of \( \mathcal{F}_t \) (the filtration where \( X \) lives), and of the microstructure noise. Suppose that, as \( n \rightarrow \infty \), \( \max(\tau_{i,j}+1 - \tau_{i,j}) = \Theta_p(1) \), and
\[
\sum_{j=0}^{n-1} (\tau_{i,j+1} - \tau_{i,j})^3 = \Theta_p(n^{-6}).
\] (11)

Let \( K_n \) be the number of blocks in \([0, T]\). In terms of the relationship between the \( \Delta \tau_i \)'s, \( K_i \)'s, \( K_n \), and \( n \), we note that in an average sense \( \bar{M} = n/K_n \), while at the same time, \( \bar{\Delta} \tau = T/K_n \). This means that \( \bar{M} = n \Delta \tau + T \). We shall assume that this condition holds for each block in an order sense, which motivates the following:

Condition 5 (Orders of \( M \) and \( \Delta \tau \)). We assume that\(^{12}\)
\[
M_{n,i} = \Theta_p(n^{1/2} \Delta \tau_{n,i}) \text{ exactly} \quad (12)
\]
\[
\Delta \tau_{n,i} = \Theta_p(n^{-1/2}) \text{ or smaller} \quad (13)
\]
\[
\Delta \tau_{n,i}^3 = \Theta_p(n^{1/3}) \text{ or smaller} . \quad (14)
\]

We note that the framework permits us to work with equisized blocks in clock time, i.e., \( \Delta \tau_{n,i} = \Delta \tau = T/K_n \), independently of \( i \). This also permits us to work with equisized blocks in transaction time, i.e., \( \Delta \tau_{n,i} = \Delta \tau = n/K_n \), independently of \( i \). Or something more complicated. This choice is controlled by the econometrician.

2.5. Location of the efficient price: decomposition theorems, and how to avoid the pulverisation of jumps

We now obtain the characterisation of the estimate \( \hat{X}_i \) of the latent efficient price process in block \( i \). The following theorem suggests that, to first order, the \( M \)-estimation averages the continuous part of the signal \( X \), but treats the jumps and the noise \( \epsilon_j \) robustly.

\(^{10}\) We have omitted the infinitely many jumps case since small jumps can in many cases be absorbed into the continuous part via contiguity (Zhang, 2007).

\(^{11}\) If \( E \psi(x) \neq 0 \) there will be a nonrandom bias in \( \hat{X}_i \) which is constant as a function of \( i \). Since most estimators only depend on increments \( \Delta \hat{X}_i = \hat{X}_i - \hat{X}_{i-1} \), this bias disappears in application.

\(^{12}\) A consequence of (12)–(13) is that \( M_i \Delta \tau_i = \Theta_p(1) \). On the other hand, from (12) and (14), we obtain \( M_i \Delta \tau_i^{-1} = \Theta_p(\Delta \tau_i^{-3}) \). Finally, if one wishes to think of \( \Delta \tau_i = O_p(n^{-1/2}) \) (which is not required), then (12) means that \( M_i \Delta \tau_i^{-1} = \Theta_p(n^{1/2}) \) exactly. Meanwhile, (13)–(14) is the same as \( 1 \leq \alpha < 6/5 \).
2.5.1. A first decomposition theorem

**Theorem 1** (Fundamental Decomposition of Estimator of Efficient Price). Let \( \hat{X}_{n,i} \) be the M-estimator in block \( i \), defined by (9). Assume **Condition 1A**, and also **Conditions 2**–**5**. Also we suppose that \( \hat{X}_i \) is either the median, or the estimating equation (9) has a unique solution with probability tending to one as \( n \to \infty \). As above, let \( M_{n,i} \) be the number of observations in block \( i \). Finally, let \( \hat{\theta}_{n,i} \) be the M-estimator based on the \( \epsilon'_i = \epsilon_{t_{n,i}} + J_{t_{n,i}} - J_{t_{n,i-1}} \), i.e.,

\[
\sum_{t_{n,i-1} \leq t_{n,i} < t_{n,i+1}} \psi'(\epsilon_{t_{n,i}} + J_{t_{n,i}} - J_{t_{n,i-1}} - \hat{\theta}_{n,i}) = 0, \tag{15}
\]

and similarly for the median. Then

\[
\hat{X}_{n,i} = \hat{\theta}_{n,i} + X_{t_{n,i-1}} + O_p(\Delta r_{n,i}/2).
\]

If we also assume **Condition 1B**, then

\[
\hat{X}_{n,i} = \hat{\theta}_{n,i} + X_{t_{n,i-1}} - \sum_{t_{n,i-1} \leq t_{n,i} < t_{n,i+1}} (X'_{t_{n,i}} - X'_{t_{n,i-1}}) \psi'(\epsilon_{t_{n,i}} - \hat{\theta}_{n,i}) \psi'(\epsilon_{t_{n,i}} - \hat{\theta}_{n,i}) + O_p(\Delta r_{n,i}).
\]

The above result shows that when there are no jumps in interval \([t_{n-1}, t_n]\), \( \hat{X}_n = \hat{\theta}_n + \hat{\theta}_n + X_{t_{n-1}} \), where \( \hat{X}_n \) is the block average. In this case, therefore, (17) cleanly decomposes the \( \hat{X}_n \) as a (potentially robust) M-estimator for the noise, while averaging the continuous part of the signal, i.e., \( X_n \). On the other hand, when there are jumps in \([t_{n-1}, t_n] \), the noise and the jumps are to first order subject to M-estimation, cf. (16). In such intervals, the continuous part of the signal is subject to a weighted averaging. The weighting scheme is more parsimoniously spelt out in (29).

2.5.2. Noise and Jumps: Behaviour of \( \hat{\theta}_n \), and a Second Decomposition Theorem

With **Theorem 1** in hand, the behaviour of \( \hat{\theta}_n \) achieves some importance. In intervals where there are no jumps, we are back to the situation of Section 2.3, with \( \theta = 0 \). If there are jumps, we can proceed as follows.

**Definition 1** (Formal Strategy for Handling Jumps, and Observation Times). Define \( \Sigma = \sigma(\tau_{n,i}, \text{all } n, j) \) (the sigma-field generated by all the observation times) and \( \tilde{\gamma}_i = \mathcal{F}_t \vee \sigma(\gamma_{t_{n,j}}) \). In other words, we condition on the jump process and on the times. They can still, however, have a probability distribution. If we need a full filtration, including the noise, we use \( \mathcal{H}_{n,t} = \tilde{\gamma}_i \vee \sigma(\epsilon_{t_{n,j}}, t_{n,j} \leq t) \). Stable convergence\(^{13}\) is defined with respect to the filtration \( (\tilde{\gamma}_i)_{0 \leq t \leq T} \). Noise related items will converge conditionally on \( \tilde{\gamma}_i \).\(^{14}\)

**Remark 1.** From **Conditions 2**–**4**, the \( \epsilon_{t_{n,j}} \) are independent of \( \tilde{\gamma}_i \). Also, \( (X'_{t_{n,j}})_{0 \leq t \leq T} \) remains a semimartingale with respect to filtration \( (\tilde{\gamma}_i)_{0 \leq t \leq T} \).

---

\(^{13}\) Stable convergence is discussed in Rényi (1963), Aldous and Eagleston (1978), Hall and Heyde (1980, Chapter 3, p. 56), Rootzén (1980). For use in high frequency asymptotics, see Jacod and Protter (1998, Section 2.2, pp. 169-170), Zhang (2001), and later work by the same authors. Stable convergence commutes with measure change on \( \Omega \) (Mykland and Zhang (2009, Proposition 1, p. 1408)).—Note that the converging random variable need not be \( \tilde{\gamma}_i \)-measurable, cf. Zhang (2006). With this convention, we suppress the need to distinguish between stable and conditional convergence. For discussions of stable convergence of instantaneous quantities, see Zhang (2001), Mykland and Zhang (2008).

\(^{14}\) The is similar to the dichotomy in Zhang et al. (2005), Zhang (2006).

**Definition 2** (The Meaning of an Interval having Jumps). The intention of the following is to deal with the problem that a small number of jumps can occur anywhere in a large number of intervals, albeit with small probability.\(^{15}\) Define, as a function of the underlying \( \omega \in \Omega \),

\[
i_{n,k} = i_{n,k}(\omega) = \text{ the kth } i \text{ such that } |\Delta f_{n,i}(\omega)| > 0.
\]

Suppose that there are \( N \) jumps in total in \([0, T]\), then there are at most \( N' \) such \( i_{n,k} \), with \( N' \leq N \). Set

\[
J_n = \{ i_{n,k} : k = 1, \ldots, N' \}.
\]

These are the intervals with jumps. The set \( J_n = \{ 1, \ldots, K_n \} - J_n \) is the set of intervals without jumps.

**Remark 2** (Asymptotically, each interval has at most one jump). Let \( \zeta_k \) be the time of the \( k \)th jump. There are eventually, for \( n \geq n_0 \),\(^{16}\) at most one jump in each interval \([\tau_{n,i-1}, \tau_{n,i}]\). Hence

\[
\zeta_k \in [\tau_{n,k-1}, \tau_{n,k}).
\]

For \( n \geq n_0 \), Eq. (20) can serve as definition of \( i_{n,k} \), in lieu of (18).

**Notation 2.** There is an ambiguity in notation in connection with the symbol \( \Delta f_{n,i} \), which means \( f_{n,i} - f_{n,i-1} \). We emphasise that \( \Delta f_{n,i} \) only depends on the process \( X \), and not on \( n \). This is the only instance where we use this meaning of \( \cdot \Delta \). In all other cases, \( \Delta \) refers to an increment on the grid of the \( \tau_{n,i} \), or the grid of the \( \tau_{n,j} \).

We are now in a position to define what \( \hat{\theta}_n \) actually estimates.

**Definition 3** (Fraction of Observations before a Jump, and Target for \( \hat{\theta}_n \)). If \( i = i_{n,k} \in J_n \), we proceed as follows. By **Remark 2**, there is, for \( n \geq n_0 \), only one jump in each such interval \( i_{n,k} \). When this happens, let \( M_{n,\alpha_{n,k}} = \#\{ i_{n,j} \in [\tau_{n,i-1}, \zeta_k] \} \) and \( M'_{n,\alpha_{n,k}} = M_{n,\alpha_{n,k}} - M'_{n,\alpha_{n,k}}\). Set

\[
\alpha_{n,k} = \frac{M'_{n,\alpha_{n,k}}}{M_{n,\alpha_{n,k}}}.
\]

Also let

\[
\theta_{n,\alpha_{n,k}} = h(\alpha; \alpha_{n,k}) \tag{22}
\]

where the function \( (\delta, \alpha) \to h(\delta; \alpha) \) is implicitly defined as \( h \) in the other words

\[
F(h; \alpha, \delta) = 0 \quad \text{where}
\]

\[
F(x; \alpha, \delta) = \alpha f(x) + (1 - \alpha) f(x - \delta) = 0 \quad \text{and}
\]

\[
f(x) = E \psi'(\epsilon - x) = 0.
\]

Observe that \( (\delta, \alpha) \to h(\delta; \alpha) \) exists and is unique since, by **Condition 3**, \( x \to F(x; \alpha, \delta) \) is continuous and strictly decreasing, with \( F(0; \alpha, \delta) = (1 - \alpha) f(-\delta) \) and \( F(\delta; \alpha, \delta) = \alpha f(\delta) \). By the same condition, if \( \delta > 0 \), \( f(\delta) < 0 < f(-\delta) \), and vice versa for \( \delta < 0 \).

We can thus characterise the behaviour of \( \hat{\theta}_{n,i} \).

\(^{15}\) This can occur, for example, if the jumps come from a Poisson process, and the intervals \([\tau_{n-1}, \tau_n]\) are equidistant. In this case, conditional on the total number of jumps \( N \), the probability of having at least one jump in any nonrandom interval \( i \) is easily seen to be \( 1 - K^{-N} \), cf. (Ross, 1996, Chapter 2.3).

\(^{16}\) Where \( n_0 \) can depend on \( \alpha \).
Theorem 2 (\(\hat{\theta}_n\) in All Intervals, Including Those Containing Jumps). Assume the first set of conditions in Theorem 1. Recall that \(K_n\) is the number of blocks, and let \(i_n\) be a sequence of indices \((1 \leq i_n \leq K_n)\) as \(n \to \infty\). Then

\[
\hat{\theta}_{n,i_n} = \theta_{n,i_n} + \eta_P(1)
\]  

where

\[
\theta_{n,i} = 0 \quad \text{for } i \in \mathcal{J}_n \tag{24}
\]

Also, conditionally on \(\mathcal{F}_n\),

\[
M_{n,i_n}^{1/2}(\hat{\theta}_{n,i_n} - \theta_{n,i_n}) \approx N(0, \sigma_{n,i_n}^2) \tag{26}
\]

where

\[
\sigma_{n,i_n}^2 = \begin{cases} 
\dfrac{f_i(0)}{f_i(1)^2} & \text{for } i \in \mathcal{J}_n \\
\alpha_n f_i(\theta_{n,i_n,k}) + (1 - \alpha_n) f_i(\theta_{n,i_n,k} - \Delta J_{k,i}) & \text{for } i = i_{n,k} \in \mathcal{J}_n
\end{cases}
\]

and where \(f_i(x) = \text{Var}(\psi(e - x))\).

Furthermore, if we also assume Condition 1.B, then the decomposition (17) can be sharpened, as follows:

**Theorem 3** (Sharper Decomposition of the Efficient Price: The Continuous Part of the Signal Treated via Means of \(X^c\)). Assume the framework and conditions of Theorem 2, as well as Condition 1.B. Define means of \(X^c\) (overall, and before and after the jump) by

\[
X_{n,i_n}^c = \frac{1}{M_{n,i_n}} \sum_{i_{n,k} \leq i_n \leq i_n} X_{i_{n,k}}^c \quad \text{and} \quad \tilde{X}_{n,i_n}^c = \frac{1}{M_{n,i_n}} \sum_{i_{n,k} \leq i_n \leq i_n} X_{i_{n,k}}^c
\]

Also define the jump-adjusted mean of \(X^c\) as

\[
\tilde{x}_{n,i_n}^{c,\text{adj}} = \begin{cases} 
\tilde{X}_{n,i_n}^c & \text{for } i \in \mathcal{J}_n \\
(1 - \gamma_{n,k}) X_{i_{n,k}}^c + \gamma_{n,k} \tilde{X}_{i_{n,k}}^c & \text{for } i = i_{n,k} \in \mathcal{J}_n
\end{cases} \tag{28}
\]

where the weights \(\gamma_{n,k} = \alpha_n f_i'(\theta_{n,i_n,k})/f_i'(\theta_{n,i_n,k}; \Delta J_{k,i}, \alpha_n,k)\), where \(f\) and \(F\) are defined in (23).

Then

\[
\hat{\theta}_{n,i_n} = \hat{\theta}_{n,i_n} + X_{i_{n},i_{n}-1} + \Delta t_{n,i_n}^{1/2} T_{n,i_n} + \eta_P(\Delta t_{n,i_n}^{1/2} M_{n,i_n}^{-1/2}) \tag{29}
\]

where

\[
T_{n,i_n} = \Delta t_{n,i_n}^{1/2} \left( \tilde{x}_{n,i_n}^{c,\text{adj}} - X_{n,i_n}^{c,\text{adj}} \right) \tag{30}
\]

We see that in all of (25), (27), and (30), the expressions for the jump case \((i \in J)\) reduce to those of the no-jump case \((i \notin J)\) by setting \(\Delta J = 0\). To see why (29) is an improvement on (17), observe that while the former expression has \(M_{n,i_n}^{-1/2}\) different weights for the \(X^c_{j_n} - X^c_{n,i_n}\), the formulae (28) and (30) has only one \((i \in J)\) or two \((i \notin J)\) such weights. This makes it clear that the main remainder term \(T_{n,i_n}\) is a (possibly two-weighted) average of the continuous evolution of the process \(X\). This sets the stage for analysing \(T_{n,i_n}\) in Section 2.7, from which we can obtain a synthesis for the M-estimation method in Section 2.8.

Remark 3 (The Form of our Central Limit Theorems). The Eq. (26) is a bona fide central limit theorem, as follows. When we say that \(Z_{n,1} \approx Z_{n,2}\), we mean that the two probability distributions are close in the sense of a metric that corresponds to convergence in law, such as the Prokhorov metric (Billingsley, 1995). We resort to this formulation because both sides in (26) are moving with \(n\). Not only is the left hand side a triangular array, but the right hand side is also a moving target. The latter is the case both because \(i_n\) moves, but also because, when \(i_n\) is of the form \(i_{n,k} \in \mathcal{J}_n\), then \(\alpha_n,k\) is also not necessarily convergent. For similar reasons, we shall resort to this formulation in all our limit theorems.

For the case where there is no jump in an interval, an even sharper decomposition is needed for our global results in Section 4. Such a result is developed in Appendix A.2.

2.5.3. Going beyond pre-averaging avoids the pulverisation of jumps

As a corollary to Theorems 2–3, we can define the effective\(^{18}\) jump signal process as

\[
\hat{J}_{n,i_n} = \hat{\theta}_{n,i_n} + J_{n,i_n-1} \tag{31}
\]

A first order consequence of (29) is that

\[
\hat{X}_{n,i_n} = \hat{J}_{n,i_n} + \tilde{X}_{n,i_n-1} + \text{higher order terms}
\]

and the theorem provides the higher order terms.

From (22) and (23), we note that in the case of pre-averaging, \(\psi(x) = x\), the jump \(\Delta J_{k,i}\) is pulverised: \(\tilde{\theta}_{n,i} = (1 - \alpha_n,k) \Delta J_{k,i}\), so that (asymptotically) a fraction of \((1 - \alpha_n,k)\) of \(\Delta J_{k,i}\) is allocated to \(J_{n,i}^j\), while the remaining (fraction \(\alpha_n,k\)) is allocated to \(J_{n,i+1}^j\).\(^{19}\) In other words, fraction \((1 - \alpha_n,k)\) of the jump is allocated to time \(t_{n,i}\), while the rest is allocated to time \(t_{n,i+1}\).\(^{20}\) The implication is that pre-averaged data dampen the size of a jump by a substantial fraction, and this may further affect a wide range of statistics.\(^{21}\)

As a contrast to pre-averaging, we now consider the case where \(\psi\) has a more general form, \(f(x) = E(\psi(e - x))\), which now depends on the distribution of \(e\). Since the size of the noise is presumably small, one can consider the case where \(e\) has cumulative distribution function \(G(\cdot,v)\), and see what happens to \(f(x)\) when \(v \to 0\). Obviously, \(f(x) \approx -\psi(x) + o(1)\) as \(v \to 0\). A deeper investigation might take the form of an expansion in \(v\), but is beyond the scope of this paper.\(^{22}\) We shall here use a crude (but easy-to-see) bound, based on \(h_0(\delta; \alpha)\), which is obtained by solving (23) with \(\psi\) is lieu of \(f\), i.e.,

\[
\alpha \psi(h_0) + (1 - \alpha) \psi(h_0 - \delta) = 0 \tag{33}
\]

Proposition 1 (Crude Bound on the Effect of Noise). Let \(\epsilon \in [0, v] > 0\), be a collection of random variables so that \(|\epsilon_i| \leq v\). Assume Condition 1.A, and that for each \(v\), the function \(x \to E(\epsilon(x + \epsilon'))\) is strictly increasing in a neighbourhood of \(x = 0\). Suppose that \(h_0\) is given by (23). Then, for all \((\alpha, \delta)\) so that (33) has a unique solution, \(|h_0(\delta) - h_0(\delta)| \leq v\)\(^{23}\).

\(^{17}\) For the case \(i \in \mathcal{J}_n\), we are in conformity with the discussion in Section 2.3 and also our Condition 3. The definition of \(a^c\) is as in (8). The same applies to (25).

\(^{18}\) As opposed to “efficient”.

\(^{19}\) This is in view of (22).

\(^{20}\) This is an asymptotic consideration, but it will be approximately true for finite \(n\) since \(\theta_{n,k}\) is the limit of \(\tilde{\theta}_{n,k}\) in (29).

\(^{21}\) Pre-averaging followed by TSRV may be an exception to this. We shall also see in Section 5 another example of a construction which is immune to jump-pulverisation. However, even in that example, one cannot set standard errors under pulverised jumps.

\(^{22}\) A more incisive investigation would presumably include the confinement to large jumps, and an expansion of the error term \(f(x) + \psi(x)\). This can presumably be carried out with a combination of contiguity (Zhang, 2007) and Laplace type methods for the asymptotic expansion of integrals, see, for example Jensen (1995, Chapter 3).

\(^{23}\) For symmetric \(\epsilon\), the approximation will in most cases be of order \(O(v^2)\).
We now consider the Huber form $\psi_c$, including $c = 0$ (the median) (Options 2 and 3 in Section 2.3; $c = +\infty$ corresponds to the mean). It is easy to see that if $|\delta| > 2c$ ($\delta$ is a largish jump, in other words), then the solution $h_{c,0}$ of (33) with $\psi_c$ is

$$h_{c,0}(\delta; \alpha) = \begin{cases} 
\delta - c \frac{\text{sign}(\delta)}{1 - \alpha} & \text{for } \alpha < \frac{1}{2} \\
\frac{c}{\alpha} \frac{1 - \text{sign}(\delta)}{1 - \alpha} & \text{for } \alpha > \frac{1}{2} 
\end{cases} \quad (34)$$

The ideal solution, would be to get $h_{c,0}(\delta; \alpha) = \delta$ when $\alpha < \frac{1}{2}$, and zero otherwise. This would avoid breaking up the jump. From (34) we see that the perfect estimator is thus the median, $\psi_0$. It is worth noting that this is not only a large sample result. When using the median, it is easy to see that the allocation to $[\tau_{i-1}, \tau_i)$ or $[\tau_i, \tau_{i+1})$ will happen by majority voting, cf. Fig. 2 and its caption. However, since one is most worried about large jumps (Zhang, 2007), an estimating function of the form $\psi_c$ for some $c > 0$ will, for small noise, be adequate.

Also for $c > 0$, there is an aspect of majority voting. If $\alpha < \frac{1}{2}$, the majority of the observations in the interval happen after the jump. The contamination is then limited by $c$ in the direction away from $\delta$. On the other hand, $\alpha > \frac{1}{2}$, the absolute value of the estimate $|h(\delta)|$ is maximally $c$. Similarly, if $h_{c,v}$ if formed from (23) with a contaminated $\psi_c$, and the contamination $\epsilon$ has absolute value bounded by $v$, if $v$ follows from Proposition 1 that

**Theorem 4.** Assume the conditions of Proposition 1. Also assume that $|\delta| > 2c$. Then

$$|h_{c,v}(\delta) - \delta| < c + v \text{ for } \alpha < \frac{1}{2}$$

$$|h_{c,v}(\delta)| < c + v \text{ for } \alpha > \frac{1}{2}. \quad (35)$$

To summarise, (34)-(35) say that, by majority decision, the main part of a large jump in interval $i$ will be allocated to one interval, either interval $i$ or interval $i + 1$. In other words, the jump will be recorded as having happened at either $\tau_i$, or $\tau_{i,i+1}$. The amount of jump allocated to the other interval is maximally $c$ or $c + v$, respectively. Under pre-averaging, on the other hand, up to half the jump ($\delta/2$) can be allocated to the other interval.

When there is noise, M-estimation is thus not perfect. But it pulverises large jumps much less than does pre-averaging.

**Remark 4 (Is Pulverisation a Problem?).** We would like to emphasise that pulverisation is not always a problem. When estimating the quadratic variation of $X$ under pre-averaging, and when using overlapping blocks, the problem disappears. A jump then occurs once in the first increment of the pre-averaging statistic, once in the second, once in the third, and so on. By summing over all such statistics, every jump then gets exactly the same factor in front.

It is not known whether this happy state of affairs would extend to any other statistics, or to irregularly spaced times (the latter even for the estimation of quadratic variation). For example, for rolling blocks of equidistant times, for the problem to be discussed in Section 5.1, the only previously known solution (in the presence of microstructure noise) is based on linear combinations of estimators of different powers of jumps and volatility (Jacod and Protter, 2012, Chapter 16.5, pp. 521–563), Aït-Sahalia and Jacod (2014, Appendix A.4, p. 496–502).

It is an interesting and important problem to try to determine to what extent rolling blocks can mitigate the pulverisation for a general class of problems. This is beyond the scope of this paper, but the question is indeed central.

With the technology of this paper (non-overlapping blocks), there are several possible inference situations. In some cases, such as jump detection, the pulverisation is a major phenomenon that has to be taken account of. One really wants the largest reading possible. In some other cases, the knowledge that pulverisation occurs can help avoid bungled estimators. One such example is the estimator in Section 5.1.

Another classical situation where pulverisation can be avoided is by leaving one space between each $\hat{X}_{n,i}$ in Bipower Variation. From Table 3 in Section 5.1, it is clear that

$$\sum_{i=1}^{\lfloor n/3 \rfloor} |\hat{X}_{n,i}||\hat{X}_{n,i-1}| = \sum_{i=1}^{\lfloor n/3 \rfloor} |\hat{X}_{n,i}||\hat{X}_{n,i-1}| + \sum_{i=1}^{\lfloor n/3 \rfloor} |\hat{X}_{n,i}| - \theta_{n,h_{\alpha}} + \theta_{n,h_{\alpha}} + o_{\alpha}(1).$$

One therefore does not get rid of the jumps except by completely avoiding the pulverisation ($\theta_{n,h_{\alpha}} = 0$ or $= \Delta_{\hat{X}_{n}^2}$). We have here used the notation $\hat{X}_{n,i}$ from Section 5.1. On the other hand, $\sum_{i=1}^{\lfloor n/3 \rfloor} |\hat{X}_{n,i}||\hat{X}_{n,i-2}| = \sum_{i=1}^{\lfloor n/3 \rfloor} |\hat{X}_{n,i}||\hat{X}_{n,i-2}$. This latter equality is very much in the spirit of the original work by Barndorff-Nielsen and Shephard (2002, 2004). The analysis may now be completed without further technology, but for reasons of space we leave the details for the reader.

2.5.4. M-estimation and efficiency

Apart from a potentially better treatment of jumps, M-estimation also offers the possibility of greater efficiency. A main difference between general $\psi$ and pre-averaging, however, lies in the behaviour of $Z_i = M^{1/2}(\hat{\theta}_i - \theta_i)$, and here the choice of $\psi$ may affect the asymptotic variance of estimators. If the noise is Gaussian, the asymptotic variance of $Z_i$ itself is, of course, minimised by pre-averaging, but this will not be the case for other noise distributions (Huber, 1981). For iid data, $\psi$ can be chosen as the derivative of the log density of the data (Stone, 1974, 1975). We conjecture that this methodology can apply here as well, though such a development would be beyond the scope of this paper.

2.6. Intra-block behaviour

To find a compact characterisation of the error in M-estimation, we shall use the following concept.
We shall see various moments of $I$ appearing in the theorems below. There are two strategies for how to handle these moments. One is to plug in the actual times (in a data analysis). For theoretical or applied purposes, one can alternatively impose the condition that the times are approximately equispaced within blocks $[\tau_{n,i−1}, \tau_{n,i})$. This can take the following three forms:\footnote{As seen in Zhang (2011)}, such an assumption also permits useful subsampling arguments.

**Definition 4** (Intra-Block Behaviour). Define the random variable $I_i = I_{n,i}$ inside each block $i$ as follows. Let $t_{0j} = t_{n,0}$ be the first $t_j \in [\tau_{n,i−1}, \tau_{n,i})$, and set, for $j = 1, \ldots, M_{n,i} − 1$, $I_{n,i} = \begin{cases} 
M_{n,i} − j & \text{with probability } \frac{\Delta t_{0+j}}{\Delta t_i} \\
1 & \text{with probability } \frac{t_{0j} − \tau_{n,i−1}}{\Delta t_i} \\
0 & \text{with probability } \frac{\tau_i − t_{0j} + M_{n,i} − 1}{\Delta t_i} .
\end{cases} \quad (36)

We shall see various moments of $I$ appearing in the theorems below. There are two strategies for how to handle these moments. One is to plug in the actual times (in a data analysis). For theoretical or applied purposes, one can alternatively impose the condition that the times are approximately equispaced within blocks $[\tau_{n,i−1}, \tau_{n,i})$. This can take the following three forms:\footnote{As seen in Zhang (2011)}, such an assumption also permits useful subsampling arguments.

**Definition 5** (Regular Times). A sequence of times $t_{n,i}$ will be said to be “regular” provided, for any sequence $t_{n,i} \in [1, K_n]$, $n \to \infty$, $I_{n,i}$ converges in law to a uniform $(0,1)$ random variable.

**Example 2.** The following generating processes give rise to regular times. See also Table 1.

T1. Equidistant times. This is where $\Delta t_{n,i} = T/n$. There is no reason to use anything but equized blocks, and here clock time and transaction time coincide. This is a common assumption in the literature.

T2. Mildly irregular times. This is where $t_{n,i} = f(j/n)$. We shall for simplicity assume that $f$ is continuously differentiable and increasing, and nonrandom. This assumption (or variants thereof) has been used by Zhang (2006) and Barndorff-Nielsen et al. (2008).

T3. Time varying Poisson Process Times. This is where $t_{n,i}$ is the $j$th observation from a Poisson process with intensity $\lambda_n(t)$. We shall for simplicity assume that the function $t \to \lambda_n(t)$ is continuously differentiable, and nonrandom. In order to make points denser as $n \to \infty$, we impose $n\lambda_n(t) \leq \lambda_n(t) \leq n\lambda_n + 1$.

We note that Assumption T3 is quite different from Assumption T2, in that, for example, the asymptotic quadratic variation of time doubles under T3 relative to T2 (Mykland and Zhang, 2012, Example 2.24, p. 148). Note that all of conditions T1–T3 satisfy Condition 4 (ibid, Example 2.19, p. 138–139).

2.7. After the noise and the jumps: averaging the continuous part of signal gives rise to a form of microstructure

Section 2.5 details the estimation error $\hat{\theta}_i - \theta_i$ from the microstructure noise and the jump component $J$ of the efficient price. We now investigate the estimation error from the continuous evolution of the efficient price $X_t$.

We shall here see that the error which comes from estimating the mean of the efficient price is asymptotically normal.

**Definition 6.** Define the returns of the continuous part of the efficient price in block $i$ by $R_{n,i} = \Delta t_{n,i}^{-1/2} (X_{\tau_{n,i}} - X_{\tau_{n,i−1}})$.

Meanwhile, the part of the estimation error which is due to continuous evolution of the signal is

$$S_{n,i} = \Delta t_{n,i}^{-1/2} (\hat{X}_{n,i} - X_{\tau_{n,i−1}} - \hat{\beta}_i). \quad (38)$$

Recall from the development in Section 2.5 that

$$S_{n,i} = T_{n,i} + \Omega_n(M_{n,i}^{1/2}) \quad (39)$$

where $T_{n,i}$ is the weighted mean of the $X_{\tau_{n,i}} - X_{\tau_{n,i−1}}$ given in (30) in Section 2.5.2. In the case where there is no jump in the interval $[\tau_{n,i−1}, \tau_{n,i})$, one retrieves straight pre-averaging of the signal:

$$T_{n,i} = \Delta t_{n,i}^{-1/2} (\hat{X}_{n,i} - X_{\tau_{n,i−1}}). \quad (40)$$

From standard martingale central limit considerations, $R_{n,i}/\sigma_{n,i}$ is asymptotically $N(0, 1)$. We further obtain

**Theorem 5** (Asymptotic Regression and Asymptotic Variance). Assume Conditions 1.B and 2–5. Then there is a coefficient $\beta_{n,i}$ and a covariance matrix $C_{\beta_{n,i}}$ so that $\hat{T}_{n,i} = \hat{\beta}_{n,i} R_{n,i}$ and $\tilde{S}_{n,i} = S_{n,i} - \beta_{n,i} R_{n,i}$ (41) (which are identical up to $O_p(M_{n,i}^{1/2})$) are asymptotically independent of $R_{n,i}$ given $\gamma_T$. Also, $(R_{n,i}, \hat{T}_{n,i})/\sigma_{n,i}$ are asymptotically independent, specifically $N(0, C_{\beta_{n,i}})$, \footnote{Recall Remark 3.} where

$$C_{\beta_{n,i}} = \begin{pmatrix} 1 & 0 \\ 0 & v_{n,i}^2 \end{pmatrix}. \quad (42)$$

The convergence in law is stable.\footnote{Recall Footnote 13.} The quantities $\beta_{n,i}$ and $C_{\beta_{n,i}}$ depend only the structure of the times $t_{n,i}$ and on the jump process $J$. When there is no jump in $[\tau_{n,i−1}, \tau_{n,i})$,

$$\beta_{n,i} = E(I_{n,i}) \text{ and } v_{n,i}^2 = \text{Var}(I_{n,i}). \quad (43)$$

When there is one jump\footnote{The sequence of intervals may then follow a scheme akin to the one described in Section 2.5.2.} in the interval $[\tau_{n,i−1}, \tau_{n,i})$, $\beta_{n,i}$ and $v_{n,i}^2$ are given in Eqs. (B.8)–(B.9) in Appendix B.2. For regular times, the expression for $\beta_{n,i}$ in a jump interval is given by (B.11).

**Proof of Theorem 5.** See Appendix B.1.

For regular times (Section 2.6) it is easy to see that,

$$E(I_{n,i}) = \frac{1}{2}, \quad E(I_{n,i}^2) = \frac{1}{3}, \quad \text{ and } \quad \text{Var}(I_{n,i}) = \frac{1}{12}, \text{ up to } o_p(1). \quad (44)$$

**Remark 5** (Asymptotic Regressions, and the Effective Price). Apart from providing the asymptotic distribution, Theorem 5 means that (41) represent the asymptotic regressions of $T_{n,i}$ and $S_{n,i}$ on $R_{n,i}$. This matters because $R_{n,i}$ is part of the return of the efficient log price, while the remainders in the regression ($\hat{T}_{n,i}$ and $\tilde{S}_{n,i}$, respectively) are asymptotically (conditionally) independent of the return $R_{n,i}$.

In analogy with (31) in Section 2.5.3, we define the effective (still as opposed to “efficient”) continuous signal process

$$X_{\tau_{n,i}} = X_{\tau_{n,i−1}} + \Delta t_{n,i}^{1/2} \beta_{n,i} R_{n,i}. \quad (45)$$
Table 1

<table>
<thead>

For regular times,

$$X_{n,i}^{\text{e,noise}} = X_{n,i-1}^{\text{e,noise}} + \frac{1}{2}(X_{n,i}^{\text{e,noise}} - X_{n,i-1}^{\text{e,noise}}) = \frac{1}{2}(X_{n,i}^{\text{e}} + X_{n,i-1}^{\text{e}}). \quad (46)$$

For the continuous part of the signal, therefore, sanity prevails, no matter how one removes the jump in Sections 2.5.2–2.5.3.

2.8. Synthesis for the $M$-estimator: estimation error as a form of microstructure

If we combine Theorems 2–3 (in Section 2.5.2) and Theorem 5 (in Section 2.7), we obtain the following decomposition of our estimated price:

$$\tilde{X}_{n,i} = X_{n,i}^{\text{e}} + J_{n,i}^{(n)} + \tilde{\theta}_{n,i} - \theta_n + \Delta t_{n,i}^{1/2} \tilde{S}_{n,i}, \quad (47)$$

*"effective" signal

where we recall that $J_{n,i}^{(n)}$ is the effective jump signal process defined in (31) in Section 2.5.3. The effective continuous signal process is given by (45) in the previous section.

We think of the terms

$$\eta_{n,i} = \tilde{\theta}_{n,i} - \theta_n + \Delta t_{n,i}^{1/2} \tilde{S}_{n,i}, \quad (48)$$

as being noise because, having conditioned on $\theta_0$,

1. $M_{n,i}^{1/2}(\tilde{\theta}_{n,i} - \theta_n)$ is asymptotically normal and independent of the $X^n$ process. The asymptotic variance is $\sigma^2$ (from (8)) where there are no jumps, and given in Theorems 2–3 otherwise;

2. $\tilde{S}_{n,i} = T_{n,i} + O_p(\Delta t_{n,i}^{1/2})$ is also asymptotically stably normal, and independent of the continuous returns $R_{n,i}$. The (random) asymptotic variance is $\sigma^2_{n,i-1} \text{Var}(I_i)$ when there are no jumps, and given in Theorem 5 otherwise, cf. (B.9) in Appendix B.2.

The two sources of noise are also independent (conditionally on $\theta_0$). One can therefore, think of the asymptotic variances as additive. In particular, when there is no jump in the interval #i,

$$\text{AVAR}(\eta_{n,i}) = M_{n,i}^{-1} \sigma^2 + \Delta t_{n,i} \sigma^2_{n,i-1} \text{Var}(I_i). \quad (49)$$

Remark 6 (Fixed Spacings and Balanced Case). In addition to assuming that $\Delta t_{n,i} = \Delta t_0$, we also assume that we have equiprobable blocks in both transaction and clock time, i.e.,

$$\Delta t_{n,i} = M_0 \Delta t, \quad (50)$$

We here also consider that we are also in the balanced case. This is to say that both sources of noise contribute to the asymptotic variance in (49). To achieve this, $M_0^{-1}$ and $\Delta t_0$ must be of the same order, whence $M_0 = cn^{1/2}$ (up to rounding to nearest integer), so that

$$\Delta t_{n,i} = M_0 \Delta t_n = cn^{1/2} \frac{T}{n} = cTn^{-1/2}. \quad (51)$$

Here $c$ is a tuning parameter determined by the econometrician. Fixed spacings is a special case of regular times, whence $\tilde{X}_{n,i}$ has asymptotic mean (latent value) (46)–(47). If there are no jumps in interval #i, the asymptotic variance becomes

$$M_0^{-1} \sigma^2 + \Delta t_{n,i} \sigma^2_{n,i-1} \text{Var}(I_i) = n^{-1/2} \left( c^{-1} \sigma^2 + \frac{1}{12} cT \sigma^2_{n,i-1} \right). \quad (52)$$

3. The elements of a general theory: global behaviour

3.1. Contiguity and partial likelihood

We have seen in Section 2.5 that within each block, it is possible to decompose the estimator $\tilde{X}_{n,i}$ into several pieces that are each asymptotically normal: $\tilde{\theta}_{n,i}$, $R_{n,i}$, and $S_{n,i} \approx T_{n,i}$. The question we ask here is whether this asymptotic normality in each block can be transformed into normality for the entire sequence. The benefits of such an approach is that difficult-to-analyse objects such as $T_{n,i}$ can instead be handled as if they were normal.

The approach chosen here is to look at sequential normality (Gaussianity given the past). With the help of contiguity, we shall see that approximate normality can be turned into exact normality.

We shall also see that partial likelihood permits us to choose which of $\tilde{\theta}_{n,i}$, $R_{n,i}$, and $S_{n,i} \approx T_{n,i}$ that we would like to simplify to Gaussian structure.

3.1.1. Strong contiguity

Section 2 is entirely about the estimated efficient price process $\tilde{X}_t$ on a local block $i$, viz. $(\tau_{i-1}, \tau_i)$. Various statistics will then be built by aggregating functions of $\tilde{X}_t$ across blocks. We shall use the machinery of contiguity to study the behaviour of our aggregated estimators. This section explains our theoretical device of contiguity. We shall move to the global results in Section 4.

In order to clarify the structure of results, it is often helpful to move to an alternative but closely related probability distribution. Specifically begin by calling the original probability $P$. This is the one under which (1)–(3) holds. As discussed in Section 2.2 of Mykland and Zhang (2009), one can with little loss of generality move to an equivalent statistical martingale measure $P^*$ where (1) is replaced by

$$dX_t = \sigma_t dW_t + f_t. \quad (53)$$

This is because measure change commutes with stable convergence (ibid, same section, which also defines stable convergence). Note that we shall not change measure on the pure jump process $f_t$.

29 We abuse notation by using the same symbol $W$ in both (1) and (53). Our apologies.
This simplification increases the transparency of arguments. We will now define a slight generalisation of this concept. We shall consider approximate probabilities \( P_n \) under which the observations (and possibly also auxiliary variables) have exactly (and not asymptotically) the simplified structure displayed in Sections 2.5 and 2.7–2.8, and at the same time provide for \( P_n \) to be close to \( P \) (and \( P^* \)) in a way that permits easy analysis. This is accomplished by the concept of strong contiguity.

**Definition 7 (Strong Contiguity).** Let \( P_n \) be a sequence of probability distributions on a set of random variables (containing the relevant observables) \( Z_n = \{ U_{n,1}, \ldots, U_{n,n} \} \). This set \( \{ U_{n,1}, \ldots, U_{n,n} \} \) can be \( X_{n,i} \), \( i = 1, \ldots, n \) but is typically richer, cf. Section 3.1.2. Then \( P_n \) is strongly contiguous relative to \( P \) provided that:

1. \( P_n \) and \( P \) are mutually absolutely continuous on the random variables \( Z_n \).
2. There is a representation

   \[
   \log \frac{dP}{dP_n}(Z_n) = \frac{1}{2} \eta^2 + o_p(1)
   \]

   where \( L_n \) is the endpoint of a \( P_n \) martingale, and where the quadratic variation of this martingale converges in probability to \( \eta^2 \), while \( L_n \) itself converges in law stably to \( \eta N(0,1) \), where \( N(0,1) \) is independent of the underlying data.

We refer to the martingale \( L_n \) in (54) as the martingale associated with \( \log \frac{dP}{dP_n} \). Symbolically, we write \( P_n \sim P \) when the two measures are mutually strongly contiguous. More generally, both probabilities can depend on \( n \). Also, more generally, \( L_n \) can be of the form \( L'_n + B_n \), where \( L'_n \) is a \( P_n \) martingale, and \( B_n \) is the endpoint of a continuous finite variation process of order \( o_p(1) \). The quadratic variation process is exchanged between \( L_n \) and \( L'_n \). With reference to Definition 1 we also define the filtration

\[
Z_{n,i} = \sigma(U_{0,0}, \ldots, U_{n,i}).
\]

(55)

For ease of exposition, we take the process \( (J_t)_{0 \leq t \leq T} \) and the observation times as part of \( U_0 \). This is most convenient since \( (J_t)_{0 \leq t \leq T} \) is independent of \( X^\ast \) and the \( \epsilon_i \)'s. We recall that the \( J \) process and the observation times are \( \eta \)-measurable, and note that \( Z_{n,0} \subseteq \eta_0 \cdot \eta \) (Definition 1). The difference between the two types of filtration is that \( \eta \) contains all the process information up to time \( t \), while \( Z_{n,0} \) only contains snapshots. Without this distinction, the contiguity would typically not be possible.

The statements about \( L_n \) and its quadratic variation are almost equivalent, see Jacod and Shiryaev (2003), and also Mykland and Zhang (2012). It follows from the definition that \( \log \frac{dP}{dP_n}(Z_n) \) converges in law stably to likelihood ratio \( \exp(\eta N(0,1) - \frac{1}{2} \eta^2) \).

It will turn out that process structure can often be much more succinctly described under a strongly contiguous approximation. Meanwhile, the change of probability measure hardly affects inferential results. Specifically, consistency, rate of convergence, and asymptotic variance are unaffected. For example, if \( n^{1/4}(\eta y_n - y) \) converges stably to \( N(b, a^2) \) under \( P_n \), then \( n^{1/4}(\eta y_n - y) \) converges stably to \( N(b', a^2) \) under \( P \). The only alteration is therefore a possible change of \( b \) to \( b' \). Often there is no change (and \( b = b' = 0 \)) but to work out the changes, one uses \( b = b' = a \) the asymptotic covariance of \( L_n \) and \( n^{1/4}(\eta y_n - y) \). Post-asymptotic likelihood ratio correction is then carried out as in Theorems 2 or 4 of Mykland and Zhang (2009).

The background for these statements is discussed in Section 2.3–2.4 of Mykland and Zhang (2009), and this former paper implicitly uses the strong contiguity concept. We have here proceeded with a formal definition because greater complexity of the problem in the current paper requires more transparent notation and terminology.

As the name suggests, strong contiguity implies the usual statistical concept of contiguity (Hájek and Sidák, 1967; LeCam, 1986; LeCam and Yang, 2000; Jacod and Shiryaev, 2003). The stronger version is suitable for our purposes.

**Example 3 (Relationship to Equivalence of Experiments).** Our strong contiguity implies that \( P_n \) is an equivalent experiment to \( P \) (and \( P^* \)), cf. LeCam (1986), LeCam and Yang (2000). Our analysis therefore ties in with the recent literature on equivalence of experiments for high frequency data, see, in particular, Hoffmann (2008), Reiss (2011), Jacod and Reiss (2014), Bibinger et al. (2014).

3.1.2. Partial likelihood, and the target approximation

We partition the variable \( U_{n,i} = (A_{n,i}, B_{n,i}) \), where \( A_{n,i} \) are auxiliary random variables, and \( B_{n,i} \) are variables of interest for which we seek normal distribution under a contiguous measure. We shall consider the choices \( B_{n,i} \) are normalised versions of \( (R_{n,i}, S_{n,i}) \) (Theorem 10 in Section 4), or of \( S_{n,i} \) (Theorem 11 in the same section). \( A_{n,i} \) will contain the essential random variables where we do not change distribution, including \( \hat{\theta}_{n,i} \). The form of \( A_{n,i} \) is spelt out in the theorems.

We shall alter the measure on \( B_{n,i} \) given the past, while the conditional measure of \( A_{n,i} \) stays unchanged, and thereby obtaining a measure \( P_n \). In analogy with Mykland and Zhang (2009), we have the likelihood decomposition (where \( f \) is a generic density)

\[
f(U_{0,1}, \ldots, U_{n,i}, \ldots, U_{n,K}|U_0) = \prod_{i=1}^{K} f(B_{n,i}|U_{0,0}, \ldots, U_{n,i-1}, A_{n,i})
\]

\[
\times \prod_{i=1}^{K} f(A_{n,i}|U_{0,0}, \ldots, U_{n,i-1})
\]

(56)

Our contiguous change of measure then becomes the partial likelihood (Cox, 1975; Wong, 1986)

\[
\log \frac{dP^*}{dP_n}(Z_n) = \sum_i \log \left( \frac{f(B_{n,i}|U_{0,0}, \ldots, U_{n,i-1}, A_{n,i})}{f(B_{n,i}|U_{0,0}, \ldots, U_{n,i-1}, A_{n,i})} \right)
\]

(57)

The choice of variables \( B_{n,i} \) thus determines which partial likelihood one wishes to work on.

Since we seek conditional normality for the \( B_{n,i} \), the requirement in (57) is that \( f(B_{n,i}|U_{0,0}, \ldots, U_{n,i-1}, A_{n,i}) \) be a normal density with mean zero and covariance matrix \( \text{Var}(B_{n,i}|U_{0,0}, \ldots, U_{n,i-1}, A_{n,i}) \) (or some asymptotic approximation thereof).

The auxiliary variable \( A_{n,i} \) is whatever is left over from \( B_{n,i} \), and is needed to retain information about the dynamic of the system. If we let \( (\kappa_n(t_n,i-1)) \) be the process of the first four cumulants given in Section 3.2.1, then \( A_t \) contains the variables \( (\kappa_n(t_n,i-1)) \), \( \hat{\theta}_{n,i} \). If \( B_{n,i} = S_{n,i}/\sigma_n \) only, then we add \( R_{n,i}/\sigma_n \) to \( A_{n,i} \).

Why not also study \( B_{n,i} = (R_{n,i}, S_{n,i}, \hat{\theta}_{n,i})? \) The reason for this is that adding \( \hat{\theta}_{n,i} \) is the simplest part of the problem and can easily be added to our results. Also, in order to have contiguity to a normal distribution when including \( \hat{\theta}_{n,i} \) one would need \( M_t \) to be of order \( O(n^{1/2}) \). Since we operate on differences, it may be possible to make statements also without this order conditions, but this seems beyond the scope of this paper.

The above informs our definition of an approximate measure \( P_n \) which is conditionally normal for the variables \( B_{n,i} \).
Definition 8 (Target Approximation). Define $P_n$ to be the measure on the sigma-field $\mathcal{Z}_n$ given in Definition 7 for which,

$$
\mathbb{L}_{P_n}(B_{n,i} \mid U_{n,0}, \ldots, U_{n,i-1}, A_{n,i})
$$

is exactly Gaussian with mean zero and conditional covariance matrix $\text{Var}_{P}(B_{n,i} \mid U_{n,0}, \ldots, U_{n,i-1}, A_{n,i})$, while

$$
\mathbb{L}_{P_n}(A_{n,i} \mid U_{n,0}, \ldots, U_{n,i-1}) = \mathbb{L}_{P}(A_{n,i} \mid U_{n,0}, \ldots, U_{n,i-1}).
$$

(58)

Since $P_n$ is uniquely defined, we shall refer to this measure as the "canonical normal approximation" corresponding to the sequence $U_{n,i} = (B_{n,i}, A_{n,i})$.

3.2. Cumulants and the $(\kappa, r)$-process

Our strategy is to obtain contiguity by Edgeworth expanding (57) term by term. Since there are only finitely many intervals with jumps, it is enough to do this for the intervals with no jumps. We shall first work with $B_{n,i}$ as the vector $V_{n,i} = (\kappa_{n,i}(\tau_{n,i}), s_{n,i}(\tau_{n,i}), t_{n,i}(\tau_{n,i}), v_{n,i}(\tau_{n,i}))^T$. We recall from Theorem 5 in Section 2.7 that $V_{n,i}$ is asymptotically standard normal, and that when there is no jump in interval # $i$, $v_{n,i}^2 = \text{Var}(ln_{i})$. For ease of expressions, we denote $V_{n,i} = (V_{n,i}^T, V_{n,i}^T)^T$.

3.2.1. Orders of cumulants, and the $(\kappa, r)$-process

To Obtain Edgeworth expansions, we need cumulants. We show the following theorem in Appendix A–C. We call $(\kappa_{n}(\tau_{n,i}))$ the full set of such $\kappa$ with up to four indices.

Theorem 6. Assume Conditions 2, 4 and 5. Assume that there is no jump in interval # $i$. Then

$$
E(V_{n,i}^r \mid \mathcal{G}_{\tau_{n,i}}) = \Delta t_{i}^{1/2} \kappa_{n}^{r}(\tau_{n,i}) + O_P(\Delta \tau_{n,i})
$$

Cov$(V_{n,i}^r, V_{n,i}^s) \mid \mathcal{G}_{\tau_{n,i}} = \delta^{r,s} \Delta t_{i}^{1/2} \kappa_{n}^{r+s}(\tau_{n,i}) + O_P(\Delta \tau_{n,i})$

Cum$(V_{n,i}^r, V_{n,i}^s, V_{n,i}^t) \mid \mathcal{G}_{\tau_{n,i}} = \Delta t_{i}^{1/2} \kappa_{n}^{r+s+t}(\tau_{n,i}) + O_P(\Delta \tau_{n,i})$

(59)

where $(r, s, t, \tau_{n,i}) = \left\{ \delta^{-2} \sigma(X)^r_{\tau_{n,i}} \kappa_{n}^{r+s}(\tau_{n,i}) + \sigma(X)^r_{\tau_{n,i}} \kappa_{n}^{r+s+t}(\tau_{n,i}) \right\}$

$\kappa_{n}^{r+s+t}(\tau_{n,i}) = \left\{ \begin{array}{ll}
\sigma^{-2} \sigma(X)^r_{\tau_{n,i}} \kappa_{n}^{r+s}(\tau_{n,i}) + \sigma(X)^r_{\tau_{n,i}} \kappa_{n}^{r+s+t}(\tau_{n,i}) \\
\sigma^{-2} \sigma(X)^r_{\tau_{n,i}} \kappa_{n}^{r+s+t}(\tau_{n,i}) + \sigma(X)^r_{\tau_{n,i}} \kappa_{n}^{r+s+t}(\tau_{n,i}) 
\end{array} \right\}$

(60)

where $\delta^{r,s} = 1$ if $r = s = 0$ otherwise (the Kronecker delta). where "prime" denotes derivative with respect to time, so that $(\sigma(X)^r_{\tau_{n,i}}) = d(\sigma(X)^r_{\tau_{n,i}})/dt$, and where

$$
\kappa_{n}^{r+s}(\tau_{n,i}) = 2E \left\{ (\kappa_{n}^{r+s}(\tau_{n,i}))^{++} + (\kappa_{n}^{r+s}(\tau_{n,i}))^{++} \right\}
$$

(3)

$$
\kappa_{n}^{r+s+t}(\tau_{n,i}) = 2E \left\{ (\kappa_{n}^{r+s+t}(\tau_{n,i}))^{++} + (\kappa_{n}^{r+s+t}(\tau_{n,i}))^{++} \right\}
$$

(61)

$$
\kappa_{n}^{r+s+t}(\tau_{n,i}) = 2 \left\{ -\kappa_{n}^{r+s+t}(\tau_{n,i}) \kappa_{n}^{r+s+t}(\tau_{n,i}) + \kappa_{n}^{r+s+t}(\tau_{n,i}) \kappa_{n}^{r+s+t}(\tau_{n,i}) \right\}
$$

(62)

where $\Delta t_{i}^{1/2}$ is an independent copy of $\kappa_{n,i}$, and where cum1 is the expectation and cum2 is the variance.

3.2.2. Edgeworth expansion

The second leg of our development brings in Edgeworth expansions. Proofs are all in Appendix D.

Condition 6 (Validity of Formal Edgeworth Expansions). For all intervals $i$ with no jump, assume that the formal Edgeworth expansions of $\log f(U_{n,0}, \ldots, U_{n,i-1})$ and $\log f(V_{n,i} \mid U_{n,0}, \ldots, U_{n,i-1})$ around the standard normal distribution are valid up to $O_P(\Delta \tau_{n,i}^{2/3})$. In other words, one can substitute the first four cumulants of $U_{n,i}$ into the Edgeworth form and have a valid expansion, cf. (McCullagh, 1987, p. 147), and also (Mykland and Zhang, 2009, (A.13), p. 1434); in the latter, orders of $O_P(\Delta \tau_{n,i}^{2/3})$ are replaced by orders of the form $O_P(\Delta \tau_{n,i}^{4/3})$.

Remark 7 (Regularity Conditions). We have here followed an approach which does not seek to determine the conditions under which the relevant Edgeworth expansions hold. This would massively expand the paper, and is beyond its scope. For references on rigorous conditions, see Wallace (1958), Bhattacharya and Ghosh (1978), Bhattacharya and Rao (1976), Hall (1992), Jensen (1995). We also take intellectual refuge in the preface of Aldous (1989). For specific references concerning expansions of semimartingales, consult the new results in Li (2012), as well as the references in Remark 12 in Mykland and Zhang (2009). For the Edgeworth expansion of moments, see the proofs or Theorems 19.2 and 22.1 in Bhattacharya and Rao (1976), cf. also (Jensen, 1995, pp. 21–22).

It is worth putting this assumption into a form which is consistent with our definition of contiguity. Theorem 7 is a restatement of the one-period Edgeworth expansion. Proofs for this section can be found in Appendix D.

Theorem 7 (One Period Edgeworth Expansion on Likelihood Ratio Form). Assume Conditions 2 and 4–6. If interval # $i$ has no jump,

$$
\log \left(f(V_{n,0}, \ldots, U_{n,0}, \ldots, U_{n,i-1}) \right)
$$

$$
= \Delta L_{i} - \frac{1}{2} \text{Var}_{h_i}(\Delta L_{i} \mid Z_{n,i-1}) + O_P(\Delta \tau_{n,i})
$$

(62)

where

$$
\Delta L_{i} = \sum_{r=0}^{1} \frac{1}{2} \text{Var}_{h_i}(\Delta L_{i} \mid Z_{n,i-1}) + O_P(\Delta \tau_{n,i})
$$

(63)

where the Hermite polynomials for interval # $i$ are random variables given by $h_i = h_i(v) = (v' - \kappa_{n,i}(\tau_{n,i}))$ and $h_{np} = h_{np}(v) = h_i h_i - h_i h_i - h_i h_i$ [3]. We have here suppressed the notational

Note that $\kappa_{n,i} = 2\sqrt{h_i h_i - h_i h_i - h_i h_i}$ [3] in the notation of Appendix B.3, cf. in particular, (B.16).

For regular times (Section 2.6), we obtain (42) and (44) that for intervals with no jumps $\text{Var}(ln_{i}) = b_{n,i} = \frac{1}{\tau_{n,i}}$, while the three dimensional tensors $\kappa_{n,i}^{r+s+t}$ and $b_{n,i}^{r+s+t}$ are given in Table 2.
dependence on \((n, i)\) in the Hermite polynomials (but the \((n, i)\) are there) and use the following convention from McCullagh [1987, Chapter 5]: [“3”] is the sum over the three possible combinations:

\[
h_{i,1}[3] = h_{i,1} + h_{i,2} + h_{i,3}.
\]

Now set \(L_n\) as the end point of the \(P_n\)-martingale, where we sum \(\Delta L_{n,i}\) over all intervals \(i\) that have no jumps:

\[
L_n = \sum_i \left( \sum_{r=0}^{1} \frac{1}{2} \kappa_n^2(\tau_{n,i-1})h_r(V_{n,i}) + \frac{1}{3!} \sum_{r,s,i=0}^{1} \frac{1}{2} \kappa_n^2(\tau_{n,i-1})h_{r+s+t}(V_{n,i}) \right). \tag{64}
\]

**Theorem 8** (Approximation to the Partial Likelihood Ratio (57)). Assume Conditions 2, 4–6. Then the partial log likelihood (57) has the expansion

\[
\log \frac{dp}{dp_n} = \log \frac{dP}{dP_n}(Z_n) = L_n - \frac{1}{2} \text{ q.v. of } L_n + o_p(1),
\]

where “q.v.” is the discrete time predictable quadratic variation process (with filtration \(Z_{n,i}\)).

The preceding theorem is almost a statement of strong contiguity, but we need a small extra piece to get there.

**Theorem 9** (Strong Contiguity of the Partial Likelihood Ratio (57)). Assume Conditions 2, 4–6. Suppose that, for \(0 \leq t \leq T\),

\[
\Delta \tau_{n,i} \sum_{\tau_{n,i-1} \leq t} \left( \kappa_n^2(\tau_{n,i-1}) \right)^2 - \Delta \eta_n^2(t)
\]

where \(A\) runs through the index sets \(\{1\}, \{00\}, \{01\}, \{10\},\) and \(\{11\}\). Set \(\eta^2 = \eta_{n,1}^2 + (3!)^{-2} (6\eta_{n,00}^2 + 2\eta_{n,01}^2 + 2\eta_{n,10}^2 + 6\eta_{n,11}^2)\), all evaluated at \(t = T\). Let \(P_n\) be defined from \(P\) by (57), and with the choice \(B = V\) and \(A = (\kappa_n(\tau_{n,i-1}), \hat{\theta}_{n,1})\). Then \(P_n\) and \(P\) are strongly contiguous with \(L_n\) given by (64), and \(\eta^2\) given in this theorem.

4. The main one-step contiguity results

The first result is a spelling out of the properties that are derived in Section 3.2.

**Theorem 10** (Contiguity to one-step normal distribution for \((R_n, \tilde{S}_{n,i})\)). Assume Conditions 1.8–6, as well as Eq. (66) in Theorem 9. Let \(P_{n,1}\) be the canonical normal approximation corresponding to \(B_{n,1} = V_{n,i} = (R_{n,i}/\sigma_{n,i}, \tilde{S}_{n,i}/\sigma_{n,i}, \nu_{n,i})^T\). The auxiliary variables are

\[
A_{n,1} = (\kappa_n(\tau_{n,i-1}), \hat{\theta}_{n,1})
\]

1. \(P_{n,1}\) is strongly contiguous with respect to \(P\) and \(P^*\), and relative to the set \(Z_n\);
2. Under \(P_{n,1}\), \(Z_n = M^{-1/2}(\hat{\theta}_{n,1} - \theta_{n,1})\) are independent with the same distribution as under \(P\), and \(Z_n\) is independent of \(X^*\). Recall that \(\theta_{n,1}\) is zero in intervals with \(i\) with no jumps, and defined in (22) and (25) in Section 2.5.2 otherwise;
3. Under \(P_{n,1}\), \(S_{n,i}/\sigma_{n,i}, \nu_{n,i}\) are iid normal \((0, 1)\), and independent of the \(X^*\) and the \(Z\) processes, where \(\nu_{n,i}\) is given in Theorem 5. In intervals \(i\) with no jumps, \(\nu_{n,i}^2 = \text{Var}(I_{n,i})\);
4. Under \(P_{n,1}, R_{n,i}/\sigma_{n,i-1}\) is normal \((0, 1)\) and independent of \(Z_{n,i}\);
5. Eq. (54) is satisfied with \(L_n\) given by (64), and \(\eta^2\) given in Theorem 9.

We here isolate the hardest part of the result, namely the behaviour of \(\tilde{S}_{n,i}\): We obtain from **Appendix D** that

**Theorem 11** (M-estimation as additional noise). Let \(P_{n,2}\) be the canonical normal approximation corresponding to the sequences \(A_{n,1} = (\kappa_{n,1}, \hat{\theta}_{n,1}, R_{n,1})\) and \(B_{n,1} = \tilde{S}_{n,1}/\sigma_{n,1}, \nu_{n,1}\),

1. \(P_{n,2}\) is strongly contiguous with respect to \(P\) and \(P^*\), and relative to the set \(Z_n\);
2. Under \(P_{n,2}\), \(Z_{n,i} = M^{-1/2}(\hat{\theta}_{n,1} - \theta_{n,1})\) are independent with the same distribution as under \(P\), and \(Z_{n,i}\) is independent of \(X^*\);
3. Under \(P_{n,2}\), \(\tilde{S}_{n,i}/\sigma_{n,i}, \nu_{n,i}\) are iid normal \((0, 1)\), and independent of the \(X^*\) and the \(Z\) processes, where \(\nu_{n,i}\) is given in Theorem 5. In intervals \(i\) with no jumps, \(\nu_{n,i}^2 = \text{Var}(I_{n,i})\);
4. Under \(P_{n,2}\), \(X\) has the same distribution as under \(P^*\);
5. Let \(L_{n,2}\) be given as

\[
L_{n,2} = \sum_i \left( \sum_{r=0}^{1} \frac{1}{2} \kappa_n^2(\tau_{n,i-1})h_r(V_{n,i}) + \frac{1}{3!} \sum_{r,s,i=0}^{1} \frac{1}{2} \kappa_n^2(\tau_{n,i-1})h_{r+s+t}(V_{n,i}) \right)
\]

where \(\nu_{n,i}, h, \kappa\) and \(\eta^2\) are the quantities from Theorem 10. \(L_{n,2}\) satisfies (65).

**Remark 8.** Note that because of asymptotic independence, there is no asymptotic adjustment to \(L_{n,2}\) due to change of measure from \(P_{n,1}\) to \(P^*\) (Mykland and Zhang, 2009, Theorem 2, p. 1412). The exact martingale would be \(L_{n,2} = 3 \sum \Delta \tau_{n,i}^{1/2} < X^*, \sigma^2 > T\). The correction term, however, is negligible and thus \(L_{n,2}\) conforms with Definition 7.

5. Examples of application

We here present one example of application, namely the estimation of even functions of returns. Other examples of application can be found (with reference to this current paper) in the following locations: (1) Mykland et al. (2012) which addresses bi- and multi-power estimators, (2) Mykland and Zhang (2014, Section 8) which adds microstructure to the estimator of Andersen et al. (2012, 2014), and (3) Mykland and Zhang (2016), which addresses efficiency, and shows that one can think of \(\hat{X}_t\) as having an MA(1)-process structure.

5.1. Functions of returns

We here consider estimators of the “parameter”

\[
\gamma = \sum_{k=1}^{N} \hat{h}(\Delta J_{ik})
\]

where \(N\) is the number of jumps of the process \(J, \zeta_{k}\) are the actual jump times, and \(\Delta J_{ik}\) is the size of the jump of \(J\) at \(\zeta_{k}\). We take the function \(x \rightarrow \hat{h}(x)\) to be even and such that \(\hat{h}(x) = o(x^2)\) as \(x \rightarrow 0\). This is a problem which is well understood in the absence of microstructure (Jacod and Protter, 2012, Chapter 5.1, pp. 125–133).

When adding microstructure, however, the problem is substantially more difficult. We refer to the treatment for the case where \(\hat{X}_t\) is handled by pre-averaging ([Jacod and Protter, 2012, Chapter 16.5, pp. 521–563], [Alt-Sahalia and Jacod, 2014, Appendix A.4, p. 496–502]). We emphasise that, of course, the cited works deal with a much more complicated underlying process, infinitely many jumps. Also, they use overlapping blocks.

To otherwise be on the same ground as the cited authors, we assume that we are in the equispaced and balanced case, i.e., we are in the situation from Remark 6 in Section 2.8. This is only to make expressions simpler, as the Eq. (71) does not depend on spacings or blocks.

Recall the representations (46)–(47), in Section 2.8, \( \hat{X}_{n,i} = f_{i,n}^\tau + \frac{1}{2} (X_{n,i}^e - X_{n,i-1}^e) + \eta_{n,i} \), where \( \eta_{n,i} \) is given by (48) in the same section, so that

\[
\hat{X}_{n,i} = \Delta f_{i,n}^\tau + \frac{1}{2} (X_{n,i}^e - X_{n,i-1}^e) + \Delta \eta_{n,i}.
\]

We now position ourselves in the situation of Remark 2, and we shall strengthen the earlier statement to say that \( n_0 \) is such that for \( n \geq n_0 \) not only is there only one jump in each interval, but there are no other jumps within three intervals on each side. Because expressions of the form \( h(\Delta f_{n,i}^\tau) \) will provide the dominating terms in an estimator of (68), we shall need some peace and quiet in the neighbourhood to investigate each jump with due diligence.

As in Remark 2, we study the \( k \)-th jump of \( f \), at time \( \xi_k \in \{ \tau_{n,k-1}, \tau_{n,k} \} \). Note that the \( k \)-th jump takes place of the \( n_k \)-th block. The situation is then as in Table 3. Summing over one and two scales in a small neighbourhood of \( \xi_k \) then gives

**Table 3**

| \( \Delta f_{n,i}^\tau \) around jump at \( \xi_k \) |
|-----------------|-----------------|-----------------|-----------------|
| \( \Delta f_{n,i}^\tau \) | \( \Delta f_{n,i}^\tau \) | \( \Delta f_{n,i}^\tau \) | \( \Delta f_{n,i}^\tau \) |
| \( \theta_{n,i} \) | \( \theta_{n,i} \) | \( \theta_{n,i} \) | \( \theta_{n,i} \) |
| \( \Delta \eta_{n,i} \) | \( \Delta \eta_{n,i} \) | \( \Delta \eta_{n,i} \) | \( \Delta \eta_{n,i} \) |
| 0 | 0 | 0 | 0 |

\[
\sum_{i = \xi_k + 1}^{\xi_k + 2} h(\Delta f_{n,i}^\tau) = \sum_{i = \xi_k + 1}^{\xi_k + 2} h(\Delta f_{n,i}^\tau) = \sum_{k=1}^{N} (2^{\text{nd}} - 1^{\text{st}} \text{ line in (70)})
\]

\[
= \sum_{k=1}^{N} h(\Delta \xi_k) = \gamma.
\]

Our proposed estimator of (68) is, therefore,

\[
\hat{\gamma}_n = \sum_{i} h(\hat{X}_{n,i} - \hat{X}_{n,i-2}) - \sum_{i} h(\Delta \hat{X}_i).
\]

Set \( \bar{\eta}_{n,i} = \frac{1}{2} (X_{n,i}^e - X_{n,i-1}^e) + \Delta \eta_{n,i} \). Because of the balanced case assumption, \( \bar{\eta}_{n,i} = \) constant. Hence we may write

\[
\sum_{i = 1}^{K_0} h(\Delta \hat{X}_{n,i}) = \sum_{i = 1}^{K_0} h(\Delta \bar{\eta}_{n,i}) + \sum_{i = 1}^{K_0} h'(\Delta \bar{\eta}_{n,i}) \bar{\eta}_{n,i} + o_p(\Delta \tau_n^{1/2}).
\]

and

\[
\sum_{i = 1}^{K_0} h(\hat{X}_{n,i} - \hat{X}_{n,i-2}) = \sum_{i = 1}^{K_0} h(f_{i,n}^\tau - f_{n,i-2}^\tau) + o_p(\Delta \tau_n^{1/2}).
\]

Theorem 11 in Section 4 to say that under \( P_{n,2} \), the \( \Delta \xi_{n,k} \) and \( \text{and/or} \) \( \eta_{n,k} \) processes are independent of each other and of the \( \xi \) and \( \tau \) processes. We shall work with \( P_{n,2} \) until further notice.

For given \( k \), \( \Delta n^{1/2} (\bar{\eta}_{n,k-1}, \bar{\eta}_{n,k} + 2 \bar{\eta}_{n,k}) \approx \frac{1}{2} \left( \bar{\eta}_{n,k+1} + \bar{\eta}_{n,k-1} + \bar{\eta}_{n,k-2} + \bar{\eta}_{n,k+1} + 2 \bar{\eta}_{n,k} \right) \), \( \Delta \tau^{1/2} (\bar{\eta}_{n,k} - \bar{\eta}_{n,k}) \), and the approximation in law stems from \( \Delta n^{1/2} (\Delta \xi_{n,k} + \eta_{n,k}) \approx \Delta n^{1/2} (\Delta \xi_{n,k} - \eta_{n,k}) \) by combining Theorems 2–3 and 11. Under an obvious combination of stable and conditional convergence, the \( \bar{\eta}_{n,k} \approx Y_{\xi_k} \) jointly (there are only finitely many of them that matter), where \( Y_{\xi_k} \), \( j = -2, \ldots, 2 \) is defined as a five-dimensional random variable with is (conditionally on \( \xi_{\xi_k} \)) independent normal with mean zero and variance of the form

\[
\begin{align*}
\text{Var}(Y_{\xi_k}|\xi_{\xi_k}) &= \frac{4\theta^2 + 4\sigma^2}{c^2 T} + \frac{4\sigma_{\xi_k}^2}{c^2 T} \\
&\text{for } j \neq 0 \\
&\text{for } j = 0.
\end{align*}
\]

We have here again invoked Theorems 2, 5 and 11. The quantities, \( \theta^2 \), \( \sigma^2 \), \( \sigma_{\xi_k}^2 \) and \( \bar{\sigma}_{\xi_k}^2 \) are given in Eqs. (8) (Section 2.3), (27) (Section 2.5.2), and (B.9) (Appendix B.2), respectively.

Finally, with the above, \( 2 \Delta n^{1/2} (\Delta \xi_{n,k} - \eta_{n,k}) \approx Y_k \) where the \( Y_k \) are conditionally independent (given \( \xi_{\xi_k} \) of each other, and of \( Y_{\xi_k}, j \neq 1 \), \( Y_{\xi_k} \), \( Y_{\xi_k} \), \( j = -1 \)) are jointly normal with (conditional) covariance \( 2\sigma_{\xi_k}^2 \).

Meanwhile \( Y_k \) have conditional variance \( 4\sigma_{\xi_k}^2 \).

From Eq. (51), \( n^{1/4} |\gamma_n - \gamma'| \approx \frac{1}{2} (cT)^{1/2} \sum_{k=1}^{K_0} h'(\theta_{n,k}) \bar{\eta}_{n,k} + \Delta \tau_n^{1/2} + o_p(\Delta \tau_n^{1/2}), \]

and

\[
\sum_{i = 1}^{K_0} h(f_{i,n}^\tau - f_{n,i-2}^\tau) + o_p(\Delta \tau_n^{1/2}).
\]

This is all under \( P_{n,2} \), but it is easy to see that there is no contiguity adjustment (since \( h \) is an even function) back to \( P^* \) and hence \( P \). The conditional variances and covariance remain the same. This is all in analogy with Mykland and Zhang (2009, Theorem 2, p. 1412).
It is now easy to see that term #k has conditional variance
\[ v_{nk}^2 = \frac{1}{4} c T \left( 2 (h' (\theta_{n, u, k})^2 + h' (\Delta J_{nk} - \theta_{n, u})^2) \left( \frac{4}{3} \sigma^2_{\gamma} + \frac{4 \sigma^2}{c^2 T} \right) \right. \]
\[ \left. + 4h' (\Delta J_{nk}) h' (\theta_{n, u, k}) \right) \sigma^2_{\gamma} \right). \]

(78)

Hence, stably in law
\[ n^{1/4} (\hat{\gamma}_n - \gamma) \overset{d}{\rightarrow} \left\{ \sum_{k=1}^N v_{nk}^2 \right\}^{1/2} \ U \]

(79)

where \( U \) is standard normal, and independent of \( \hat{\gamma}_T \).

In other words, for this estimator, the potential pulverisation discussed in Section 2.5.3 does not impact the estimator \( \hat{\gamma}_n \), or its convergence to the target \( \gamma \), but it does impact the setting of asymptotic variance. The case for robust estimation thus also occurs in this example.

6. Conclusion

In this paper, we have taken the view that pre-averaging is a way of estimating the efficient price under market microstructure noise. This opens the possibility of using other and more robust estimators, and we have here investigated one class of these, namely M-estimators. It turned out that this procedure is robust with respect to the noise and the jumps, while averaging the continuous part of the signal.

We have two main sets of results. One is Theorems 1–4 in Section 2.5, which show that by moving from pre-averaging to pre-M-estimation, one can to a great extent avoid the pulverisation of jumps that is present in pre-averaging. M-estimation also opens the possibility for better efficiency (Section 2.5.4).

The other main result is to analyse estimators globally, as follows. Under a contiguous measure, the estimation error from M-estimation (including pre-averaging) can be seen as an additional component to the microstructure noise. This sequence of results is initiated (as a local result) in Theorem 5 in Section 2.7. The global contiguity result for our estimators are then contained in Theorems 10–11 in Section 4. The error due to contiguity can, as usual, be offset with a post-asymptotic likelihood ratio correction. We saw in Section 5 that the result is highly applicable.

As part of the development, Section 3 set up a general framework for finding contiguity results in data systems of this nature using partial likelihood and Edgeworth expansions.

An issue that has not been addressed in the foregoing is how to handle \( \hat{X} \)'s when blocks are overlapping. We conjecture that the results in the current paper will still provide consistency and the correct convergence rate. One approach may be to combine this with an “observed” standard error, based on the development in Mykland and Zhang (2014). But that is a story for another time.

Appendix A. Proofs for Section 2.5

A.1. Proof of Theorem 1

First note that as discussed in Section 4.5 of Mykland and Zhang (2012), we can assume without loss of generality that \( \sigma^2_{\epsilon} \) is bounded by a constant \( \sigma^2_{\epsilon} \) on the whole interval \([0, T]\). Also, as discussed in Section 2.2 of Mykland and Zhang (2009), we can assume that we are under an equivalent martingale measure where \( \mu_t \equiv 0 \). Set \( \epsilon'_{ij} = \epsilon_{ij} + J_j - J_{t_{i-1}} \) and \( X'_{ij} = X_{ij}^c + J_{t_{i-1}} \).

To first establish the nature of the approximation, let \( G_i = \Delta t^{-1/2} \max_{t_{i-1} \leq t \leq t_i} |X_{ij}^c - X_{ij}^c| \). We note that \( G_i = O_p(1) \). Since \( Y_j - \hat{X}_i + \epsilon'_{ij} = X'_{ij} - \hat{X}_i \),
\[ |Y_j - \hat{X}_i + \epsilon'_{ij}| = |X'_{ij} - \hat{X}_i| \]
\[ \leq |X'_{ij} - X'_{t_{i-1}}| + |X'_{t_{i-1}} - X_{t_{i-1}}| \leq \Delta t^{1/2} G_i. \]

Hence,
\[ 0 = \sum_{t_{i-1} \leq \tau < t_i} \psi(Y_j - \hat{X}_i) \leq \sum_{t_{i-1} \leq \tau < t_i} \psi(\epsilon'_{ij} - \hat{X}_i + \Delta t^{1/2} G_i). \]

In the case where (15) has a unique solution, it follows since \( \psi \) is non-decreasing that \( \hat{X}_i - (\hat{X}_i + \hat{\theta}_i) \leq \Delta t^{1/2} G_i \) eventually. Repeating the same argument on the other side yields that
\[ |\hat{X}_i - (\hat{X}_i + \hat{\theta}_i)| \leq \Delta t^{1/2} G_i = O_p(\Delta t^{1/2}). \]

(A.1)

In the case of the median, one goes through the same procedure with each of the end points of the solution interval to Eq. (9). This proves the first part of Theorem 1.

To get a more precise form of the remainder, let
\[ \delta_i = \hat{X}_i - (\hat{X}_i + \hat{\theta}_i). \]

(A.2)

In view of (A.1), we can Taylor expand safely. Since
\[ Y_j - \hat{X}_i - (\epsilon'_{ij} - \hat{\theta}_i) = X'_{ij} + J_{t_{i-1}} - \hat{X}_i \]
\[ = X'_{ij} + J_{t_{i-1}} - \hat{X}_i - \delta_i \]
\[ = X'_{ij} - \hat{X}_c - \delta_i, \]

we obtain from Taylor’s formula that
\[ 0 = \sum_{t_{i-1} \leq \tau < t_i} \psi(Y_j - \hat{X}_i) \]
\[ = \sum_{t_{i-1} \leq \tau < t_i} \psi(\epsilon'_{ij} - \hat{\theta}_i) + \sum_{t_{i-1} \leq \tau < t_i} (X'_{ij} - \hat{X}_c - \delta_i) \psi'(\epsilon'_{ij} - \hat{\theta}_i) \]
\[ + \sum_{t_{i-1} \leq \tau < t_i} \int_0^1 (X'_{ij} - \hat{X}_c - \delta_i - s) \psi''(\epsilon'_{ij} - \hat{\theta}_i + s) ds \]
\[ = \sum_{t_{i-1} \leq \tau < t_i} (X'_{ij} - \hat{X}_c - \delta_i) \psi'(\epsilon'_{ij} - \hat{\theta}_i) + O_p(M_i \Delta t_i). \]

(A.3)

where, in the final step, we have used the definition of \( \hat{\theta}_i \), the boundedness of \( \psi'' \), as well as the bound (A.1). Hence,
\[ \delta_i = \frac{\sum_{t_{i-1} \leq \tau < t_i} (X'_{ij} - \hat{X}_c) \psi'(\epsilon'_{ij} - \hat{\theta}_i)}{\sum_{t_{i-1} \leq \tau < t_i} \psi'(\epsilon'_{ij} - \hat{\theta}_i)} + O_p(\Delta t_i). \]

(A.4)

Observe that the order of the denominator in (A.4) is \( O_p(M_i) \). In particular,
\[ \hat{X}_i - \hat{\theta}_i - X_{t_{i-1}} = \hat{X}_i - X_{t_{i-1}} + \delta_i \]
\[ = \sum_{t_{i-1} \leq \tau < t_i} (X'_{ij} - X_{t_{i-1}}) \psi'(\epsilon'_{ij} - \hat{\theta}_i) \]
\[ = \sum_{t_{i-1} \leq \tau < t_i} \psi'(\epsilon'_{ij} - \hat{\theta}_i) + O_p(\Delta t_i) \]

(A.5)

thus proving the rest of Theorem 1. □

31 See Lévy (1948), and also Karatzas and Shreve (1991, Theorem 3.6.17, pp. 211-212). Alternatively, use the Burkholder–Davis–Gundy Inequalities, ibid, Theorem 3.3.28, p. 166. Observe that \( G_i \) is not \( O(1) \), cf. the discussion of the modulus of continuity of Brownian motion (ibid, Theorem 2.8.25, and Eqs. (9.26)-(9.27), p. 114.)
A.2. A sharper decomposition of the M-estimator for intervals with no jumps

For the development in Appendix C, we need a stronger result than those of Section 2.5.

**Theorem 12** (Remainder Term in the Continuous Case in the Fundamental Decomposition of the Estimator of Efficient Price). Assume Assumptions 1.B–5. Let \( \{t_1, \tau_1\} \) be a block with no jump. Set

\[
D_i = \sum_{t_1 \leq s < \tau_1} (X_s - \tilde{X}_s)(\psi'(\epsilon_i) - E\psi'(\epsilon)) + \frac{1}{2} \hat{s}^2 E\psi''(\epsilon) \tag{A.6}
\]

where \( \hat{s}^2 = \sum_{t_1 \leq s < \tau_1} (X_s - \tilde{X}_s)^2 \). Then

\[
\tilde{X}_t - X_t = \hat{\theta} + M_{\tau_1}^{-1}(E\psi'(\epsilon))^{-1} D_0 + \hat{P}(\Delta \tau_1)^{-3/2} \tag{A.7}
\]

\[
\hat{\theta} + M_{\tau_1}^{-1}(E\psi'(\epsilon))^{-1} D_0 + \hat{P}(\Delta \tau_1) \tag{A.8}
\]

Note that in view of the assumptions, \( \hat{\theta} \) is an estimator of \( \theta_0 = 0 \) (since there is no jump in the block), so that \( M_{\tau_1}^{-1/2} \hat{\theta} = \hat{P}(1) \). This follows from classical i.i.d. M-estimation, see, e.g., (Huber, 1981, Theorem 3.1, p. 133).

**Proof of Theorem 12.** We now assume that the process \( X_t \) is continuous, and will denote \( X^t \) by \( X \). Let \( s^2 \) be as in the statement of Theorem 12. We first show that, if \( \Delta \tau_1 = \sigma(t_{n, j}) \) (all \( n, j \)) \( \{\text{Definition 1}\} \),

\[
E(s^2 | \mathcal{F}_{t_{n, j}} \cap \mathcal{T}) = E_{t_{n, j}} \Delta \tau_1 M_{n, j} E(l_i(1 - l_j) + 1 + \hat{P}(1)) \tag{A.9}
\]

where \( E(l_i(1 - l_j)) \) refers to the expectation over the random variable \( l_i(1 - l_j) \), where \( l_i \) is defined in Section 2.6. To see (A.9), use the decomposition (C.1). The first term in this decomposition is handled by appealing to the moment calculation underlying the central limit argument in Appendix B.1. The second term becomes

\[
E \left\{ \frac{\Delta \tau_1 M_{n, j}^{-1}}{\sum_{t_1 \leq s < \tau_1} (X_s - \tilde{X}_s)^2} \right\} = \frac{\sigma^2}{\sum_{t_1 \leq s < \tau_1} (l_j - \tau_{t-1})} = \frac{\sigma^2}{\sum_{t_1 \leq s < \tau_1} (l_j - \tau_{t-1})} \tag{A.10}
\]

Combining the two terms yields (A.9).

To see (A.7), we continue the development from Appendix A.1, but recall that \( X_t \) is continuous. \( s \) gets the form

\[
\hat{\theta} = \tilde{X}_t - \tilde{X} \tag{A.11}
\]

Also, since \( \hat{\theta} = \hat{P}(M_{n, j}^{-1/2}) \),

\[
\sum_{t_1 \leq s < \tau_1} \psi'(\epsilon_i - \hat{\theta}) = M_{n, j} \psi'(\epsilon) + \hat{P}(M_{n, j}) \tag{A.12}
\]

and

\[
\sum_{t_1 \leq s < \tau_1} (X_s - \tilde{X}_s) \psi'(\epsilon_i - \hat{\theta}) = \sum_{t_1 \leq \tau_1} (X_s - \tilde{X}_s) \psi'(\epsilon_i - \hat{\theta}) \tag{A.13}
\]

\[
= 0 \tag{A.14}
\]

The last transition above comes from an argument similar to (A.15) (using (A.9)). The first transition in (A.12) comes from noting that \( P(\hat{\theta}) > \theta_0 = o(1) \) for any constant \( \theta_0 > 0 \). See \( \hat{\theta} = (\hat{\theta} \wedge \theta_0) \vee (-\theta_0) \). For simplicity of notation set \( A_j = \psi'(\epsilon_i - \hat{\theta}) \). As in Section 2.5.4, we let \( \tilde{t}_i = \tilde{t}_{n, j} \) be the first \( \tilde{t}_i \in \{t_1, \ldots, \tau_1\} \), and similarly \( \tilde{t}_j \) is the second such \( \tilde{t}_j \). We are interested in \( B_1 \) above \( \tilde{t}_j \). Since \( E(B_1 \mid X \cap \mathcal{T}) = 0 \), we bound \( B_1 \) in probability by observing that, by symmetry, \( \text{Var}(B_1 \mid X \cap \mathcal{T}) = (\text{Var}(A_1) + \text{Cov}(A_1, A_j)) \hat{s}^2 \). This is because \( \sum_{t_1 \leq s < \tau_1} (X_s - \tilde{X}_s)^2 \).

Theorem 12 provides a sharp decomposition of the M-estimator for intervals with no jumps.
Proof of Theorem 3. To see (29), consider separately the numerator $N_m$ and denominator $D_m$ in (17). For the numerator, $N_m = M_m - M_{m-1}k_3'$ for $j < 0$, $N_m = M_{m+1}k_2'$ for $j > 0$, and $N_m = M_mk_2'$ for $j = 0$. The result then follows.

Proof of Proposition 1. Let $F_i(\theta; \alpha, \beta)$ be as in Eq. (23), for some $|\epsilon| \leq v$. Let $h_0 = h_0 - v$. Since $F_5$ is nondecreasing and since $\epsilon + v > 0$, $F_5(h_0; \alpha, \beta) = \alpha_0 F_5(\epsilon + v - h_0) + (1 - \alpha_0) F_5(\delta + v - h_0) \leq \alpha_0 (\delta - h_0) + (1 - \alpha_0) (\delta - h_0) = 0$ by definition. By Condition 3, however, $h_0 < h_\nu$. The opposite inequality is proved in the same way.

Appendix B. Proofs of Theorem 5, and Higher Order Formulae for $(R_i, T_i)$

For simplicity of notation, we assume that $\tau_{i-1}$ and $\tau_i$ coincide with a $\tau_i$; the further generalisation is simple but tedious, and does not impact our results to the relevant order of approximation. Set

$$U_i^{(k)} = \Delta_{\tau_{i-1}}^{1/2} \sum_{\tau_{i-1} < \tau_i} \left( \frac{M - j}{M} \right)^k \Delta X_{\tau_i}^c, \quad \text{(B.1)}$$

With $R_i$ and $T_i$ as previously defined in (37) and (40). $R_i = U_i^{(0)}$ and $T_i = U_i^{(1)}$. Note that, in this order of notation,

$$\langle U^{(k)}, U^{(k')} \rangle = \Delta\tau_{i-1}^{1/2} \sum_{j=0}^{M-1} \left( \frac{M - j}{M} \right)^{k+k'} \Delta(X_i^c, X_{i+1}^c).$$

$$\text{B.1. First order behaviour of } (R_i, T_i), \text{ including proof of Theorem 5 in the continuous case.}$$

Consider first the case where there is no jump in $[\tau_{i-1}, \tau_i]$, when $S_i = T_i = O(\Delta\tau_{i-1}^{1/2})$. For the first part of the result, the form of (39) of the asymptotic covariance of $(R_j, T_j)/\sigma_{\tau_{i-1}}$ follows from (B.2).

To see stable convergence, let $\xi_i$ be another continuous Itô process, set $\Sigma = \Delta\xi_i$, and note that

$$\langle U^{(k)}, \xi_i / \sqrt{\Delta\tau_{i-1}} \rangle = \langle X_i^c, \xi_i / \sqrt{\Delta\tau_{i-1}} \rangle (1 + o_p(1)) \quad \text{and}$$

$$\langle \xi_i / \sqrt{\Delta\tau_{i-1}}, \xi_i / \sqrt{\Delta\tau_{i-1}} \rangle = \langle \xi_i, \xi_i / \sqrt{\Delta\tau_{i-1}} \rangle (1 + o_p(1)).$$

where $U^{(k)}$ is given by (B.1). “Prime” denotes derivative with respect to time, so that $(X_i^c)' = d(X_i^c)/dt$, cf. also same usage in Theorem 6 in Section 3.2.1. The CLT then yields that (with some abuse of notation)

$$\left( \frac{T_i}{R_i}, \frac{\Sigma}{\tau_i} \right)$$

$$\xrightarrow{\mathcal{L}} N \left( 0, \begin{pmatrix} \sigma_{\tau_{i-1}}^2 & \sigma_{\tau_{i-1}}^2 & \sigma_{\tau_{i-1}}^2 & \sigma_{\tau_{i-1}}^2 \sigma_{\tau_{i-1}}^2 \sigma_{\tau_{i-1}}^2 \sigma_{\tau_{i-1}}^2 \sigma_{\tau_{i-1}}^2 \sigma_{\tau_{i-1}}^2 \sigma_{\tau_{i-1}}^2 \end{pmatrix} \right). \quad \text{(B.4)}$$

A linear transformation yields that

$$\left( \frac{T_i - E(l_i)R_i}{R_i}, \frac{\Sigma}{\tau_i} \right)$$

$$\approx N \left( \begin{pmatrix} \sigma_{\tau_{i-1}}^2 & 0 & 0 \sigma_{\tau_{i-1}}^2 & 0 & 0 \sigma_{\tau_{i-1}}^2 & 0 & 0 \end{pmatrix} \begin{pmatrix} \langle X_i, \xi_i \rangle & \langle X_i, \xi_i \rangle & \langle \xi_i, \xi_i \rangle \end{pmatrix} \right). \quad \text{(B.5)}$$

This shows the result of Theorem 5 for intervals with no jump.

B.2. First order behaviour of $(R_i, T_i)$, including proof of Theorem 5 for the discontinuous case.

Assume that there is no more than one jump $\Delta J_\xi_i$ in interval $[\tau_{i-1}, \tau_i]$. This will eventually occur. For notational convenience write $\hat{\xi}_i$ for $\xi_i - \Delta J_\xi_i$. Let $T_i$ be as in (30) in Theorem 2 in Section 2.5.2. Because of asymptotic negligibility, we can take $\hat{\tau}_0 = \tau_{i-1}$ and $\hat{\tau}_{M+1} - \hat{\tau}_0 = \xi_k$. Rewriting as above,

$$T_i = \Delta\tau_{i-1}^{-1/2} D_{n-k}$$

$$\times \left( \sum_{j=1}^{M-1} \Delta X_{\hat{\tau}_j-i}^c \left( \frac{M_j - j}{M} \right) f'_{\xi_i} + \sum_{j=M+1}^{M} \Delta X_{\hat{\tau}_j-i}^c \left( \frac{M_j - j}{M} \right) f'_{\xi_i} - f'_{\xi_i} \right) \Delta J_\xi_i.$$
block. The later blocks follow by the same method but more notation. For simplicity, write $M$ for $M_1$ and $\Delta t$ for $\Delta t_1$. We do not assume equidistant spacings. – For the non-asymptotic covariance expression in \eqref{B.2}, we obtain from that
\[
\text{Cov}(U^{(k)}, U^{(k)}) = \sigma^2 E(U_{t+1}^{(k+2)})(1 + O_p(\Delta t)) \tag{B.12}
\]
since $\mathcal{A}(X^c, X^c)_t = \Delta t \sigma^2 + O_p(\Delta t^2) \, dt = \Delta t \sigma^2(1 + O_p(\Delta t))$.
– We now turn to the third cumulant, where we similarly obtain,
\[
\text{cum}_3(U^{(k_1)}, U^{(k_2)}, U^{(k_3)}) = \text{Cov}(U^{(k_1)}, U^{(k_2)}, U^{(k_3)}) \tag{3}
\]
(notation of McCullagh \citeyear{1987})
\[
= \Delta t^{-3/2} \text{Cov} \left( \sum_{j=1}^{M} \left( \frac{M-j}{M} \right)^{k_1+k_2} \right)
\times \int_{t_{j-1}}^{t_j} \sigma^2 dt \sum_{j=1}^{M-1} \left( \frac{M-j}{M} \right)^{k_3} \Delta X_0 \right) [3]
\]
\[
= \Delta t^{-3/2} \text{Cov} \left( \sum_{j=1}^{M} \left( \frac{M-j}{M} \right)^{k_1+k_2} \right)
\times \int_{t_{j-1}}^{t_j} \sigma^2 dt \sum_{j=1}^{M-1} \left( \frac{M-j}{M} \right)^{k_3} \Delta X_0 \right) [3].
\]
Now note that
\[
\text{Cov} \left( \sum_{j=i}^{M} \left( \frac{M-j}{M} \right)^{k_1+k_2} \right)
\times \int_{t_{j-1}}^{t_j} \sigma^2 dt \sum_{j=1}^{M-1} \left( \frac{M-j}{M} \right)^{k_3} \Delta X_0 \right) [3]
\]
\[
= \text{Cov} \left( \sum_{i=0}^{2} \int_0^t \sigma dX_t + \langle \sigma, \sigma \rangle_t \sum_{i=0}^{M-1} \left( \frac{M-i}{M} \right)^{k_1+k_2} \right)
\times \int_{t_{j-1}}^{t_j} \sigma^2 dt \sum_{j=1}^{M-1} \left( \frac{M-j}{M} \right)^{k_3} \Delta X_0 \right) [3]
\]
\[
= 2 \sigma^2 \sigma_0(\sigma, X)_0 \sum_{t_{j-1} \leq t \leq t_j} \left( \frac{M-i}{M} \right)^{k_1+k_2} \Delta X_0 \right) [3].
\]
where the first "\(\approx\)" is exact in the double Gaussian case \cite{2011}. Hence
\[
\text{cum}_3(U^{(k_1)}, U^{(k_2)}, U^{(k_3)}) 
\approx \Delta t^{-3/2} \sigma^2 \sigma_0(\sigma, X)_0 \sum_{t_{j-1} \leq t \leq t_j} \left( \frac{M-i}{M} \right)^{k_1+k_2}
\times \int_{t_{j-1}}^{t_j} \sigma^2 dt \sum_{j=1}^{M-1} \left( \frac{M-j}{M} \right)^{k_3} \Delta X_0 \right) [3]
\]
\[
= \Delta t^{-3/2} \sigma^2 \sigma_0(\sigma, X)_0 \sum_{t_{j-1} \leq t \leq t_j} \left( \frac{M-i}{M} \right)^{k_1+k_2} \Delta X_0 \right) [3]
\]
\[
= \Delta t^{-1/2} \sigma_0(\sigma, X)_0 \omega^{k_1+k_2+k_3} [3].
\]
To get a further handle on $\omega^{k_1k_2k_3}$, observe that
\[
E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right) = E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right)
\]
\[
= E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right) - E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right)(1 - \chi)
\]
\[
= E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right) - E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right)(1 - \chi)
\]
\[
= E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right) - \frac{1}{2} E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right) \tag{B.14}
\]
where we have used that, by symmetry, $E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right)(1 - \chi) = E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right)$, while the left and right hand side must sum to $E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right)$. From \eqref{B.14} we thus obtain that
\[
\omega^{k_1k_2k_3} [3] = E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right) \tag{3}
\]
\[
- \frac{3}{2} E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right). \tag{B.15}
\]
Using \eqref{B.15}, define $\omega^{k_1k_2k_3}$ as the quantity which arises when replacing $T$ by $\tilde{T}$, to obtain
\[
\omega^{k_1k_2k_3} [3] = E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right) \tag{3}
\]
\[
- \frac{3}{2} E \left( \bar{t}_i^k \bar{t}_j^k \bar{t}_n^k \right). \tag{B.16}
\]

Appendix C. Proof of Theorem 6: The complete cumulants

C.1. Cumulants involving $\bar{s}_i$

For expressions involving $\bar{s}_i$, we will use \eqref{A.9}, and also that
\[
\frac{\bar{s}_i^2}{\Delta t_1 M_i} = - \bar{T}_i^2 + \frac{1}{\Delta t_1 M_i} \sum_{\tau_i \leq \alpha \leq \tau_i} (X_{\alpha} - X_{\tau_i})^2 \tag{C.1}
\]
and so, for example,
\[
\text{Cov} \left( \frac{\bar{T}_i - \bar{s}_i}{\Delta t_1 M_i} | Z_{n-i-1} \right) = - \text{cum}_3(T_i | Z_{n-i-1})
\]
\[
+ \frac{1}{M_i} \sum_{\tau_i \leq \alpha \leq \tau_i} \text{cum}_3(T_i, \Delta T_i^{-1/2}(X_{\alpha} - X_{\tau_i}) \tag{C.2}
\]
\[
\Delta T_i^{-1/2}(X_{\alpha} - X_{\tau_i}) | Z_{n-i-1} = O_p(\Delta T_i^{-1/2});
\]
for the first term, this is explicitly shown in Appendix B.3, and for the second term, it follows by a very similar calculation (replace $R_i$ by $R_i^0 = \Delta T_i^{-1/2}(X_{\alpha} - X_{\tau_i})$ and proceed in the same way. By similar methods,
\[
\text{cum}_3 \left( U_{i_1}^{(k_1)}, U_{i_2}^{(k_2)}, \frac{\bar{s}_i^2}{\Delta t_1 M_i} | Z_{n-i-1} \right)
\]
\[
= - \text{cum}_4(U_{i_1}^{(k_1)}, U_{i_2}^{(k_2)}, U_{i_{n-i}} | Z_{n-i-1})
\]
\[
+ \frac{1}{M_i} \sum_{\tau_{n-i-1} \leq \alpha \leq \tau_{n-i-1}} \text{cum}_4(U_{i_1}^{(k_1)}, U_{i_2}^{(k_2)}, R_i^0, R_i^0 | Z_{n-i-1})
\]
\[
- 2 \text{Cov}(U_{i_1}^{(k_1)}, U_{i_2}^{(k_2)} | Z_{n-i-1}) \text{Cov}(U_{i_{n-i}}^{(k_2)}, U_{i_{n-i}} | Z_{n-i-1}) + \frac{2}{M_i}
\]
\[
\times \sum_{\tau_{n-i-1} \leq \alpha \leq \tau_{n-i-1}} \text{Cov}(U_{i_1}^{(k_1)}, R_i^0 | Z_{n-i-1}) \text{Cov}(U_{i_{n-i}}^{(k_2)}, R_i^0 | Z_{n-i-1})
\]
\[
+ \text{O}_p(1)
\]
\[
= 2 \text{C}^4 \left( -E(t_{i_1}^{(k_1)})E(t_{i_2}^{(k_2)}) + E \left( t_{i_1}^{(k_1)} t_{i_2}^{(k_2)} \right) \right)
\]
\[
+ \text{O}_p(1) \tag{C.3}
\]
where \( l_i' \) is an independent copy of \( l_i \). (Very similar expressions are given in Appendix B.3.) Note that the fourth cumulants do not contribute to the expression, and we have used (B.12) in the final transition. If we set

\[
\hat{U}_i^{(1)} = U_i^{(1)} - E(l_i)U_i^{(0)} \quad \text{and} \quad \hat{U}_i^{(0)} = U_i^{(0)},
\]

we obtain similarly that

\[
\begin{align*}
\text{cum}_3 & \left( \left( \hat{U}_i^{(k)}; \hat{U}_i^{(k)}; \hat{U}_i^{(k)} \right) \right) \\
&= 2\sigma_i^4 \left\{ \text{cum}_{k+1}(l_i) \text{cum}_{k+1}(l_i) \\
&\quad + E \left( \left( l_i' \right) \left( l_i - E(l_i') \right)^3 \left( l_i' - E(l_i') \right)^2 \right) \right\} + o_p(1),
\end{align*}
\]

where \( \text{cum}_1 \) is the expectation and \( \text{cum}_2 \) is the variance.

### C.2. Conditional cumulants of \( H_t \)

Recall that \( S_t = \Delta t_i^{-1/2} \left( \hat{X}_t - X_{t-1} - \hat{\theta}_t \right) = H_t + T_t. \) Set \( \hat{U}_i^{(k)} = R_i \) for \( k = 0 \) and \( \hat{S}_i = S_i \) for \( k = 1 \). Thus \( \hat{U}_i^{(k)} = U_i^{(1)} + H_i \delta_{i=0} \).

From [C.9], \( E(S_t \mid X, \Theta, \Sigma) = T_t + \Delta t_i^{-1/2} \frac{\pi}{\Delta t_i} K_t + o_p(\Delta t_i^{1/2}) \), \( \text{Var}(S_t \mid X, \Theta, \Sigma) = o_p(\Delta t_i^{1/2}) \), and \( \text{cum}_3(S_t \mid X, \Theta, \Sigma) = o_p(\Delta t_i) \). By rules for conditional cumulants (Brillinger, 1969; Speed, 1983), and since \( E(R_i \mid Z_{n,i-1}) = \left( T_t \mid Z_{n,i-1} \right) = 0 \), we obtain

\[
E(S_t \mid Z_{n,i-1}) = \Delta t_i^{1/2} \frac{\pi}{\Delta t_i} K_t + o_p(\Delta t_i^{1/2})
\]

\[
= \Delta t_i^{1/2} \frac{\pi}{\Delta t_i} \left( \frac{\pi}{\Delta t_i} K_t \right) + o_p(\Delta t_i^{1/2}) \quad \text{by (A.9)}
\]

\[
\text{Cov}(S_t, \hat{U}_i^{(k)} \mid Z_{n,i-1}) = \text{Cov}(E(S_t \mid X, \Theta), E(\hat{U}_i^{(k)} \mid X, \Theta) \mid Z_{n,i-1}) + \text{Cov}(E(S_t, \hat{U}_i^{(k)} \mid X, \Theta) \mid Z_{n,i-1}) \quad \text{by (A.9)}
\]

\[
\text{cum}_3(U_i^{(1)}; U_i^{(1)}; U_i^{(1)} \mid Z_{n,i-1})
\]

The third cumulant \( \text{cum}_3(U_i^{(1)}, U_i^{(2)}, U_i^{(3)} \mid Z_{n,i-1}) \) is given in Appendix B.3, where it is seen to be of exact order \( o_p(\Delta t_i^{1/2}) \), as required. For expressions involving \( s_i^2 \), we have used (A.9), and also the results from Appendix C.1. The third cumulant \( \text{cum}_3 \left( \frac{s_i^2}{\Delta t_i} K_t, U_i^{(2)}, U_i^{(3)} \right) \) is given by (C.5) in Appendix C.1.

Finally, set \( V_t^0 = R_t \) and \( V_t^1 = \hat{S}_t = H_t + \hat{\theta}_t. \) We obtain, with \( \hat{U} \) given in (C.4),

\[
\text{cum}_3(V_t^0; V_t^0; V_t^0 \mid Z_{n,i-1})
\]

where \( \hat{U}_i^{(k)}; \hat{U}_i^{(k)}; \hat{U}_i^{(k)} \) are given in Eq. (61) in Theorem 6. The expressions for the expectation and variance terms follow similarly.
Appendix D. Proofs for Sections 3.2.2 and 4

Proof of Theorems 7-8. The $L_n$ terms describe to main order the behaviour of $\log \frac{dP_n}{dP}$ via Edgeworth expansion. This is essentially the same arguments that take you from (A.13) to (A.21) (pp. 1434-5) in Mykland and Zhang (2009). Orders of $O_p(\Delta f^{2/2})$ are replaced by orders of the form $O_p(\Delta f^{2})$, but in compensation, there are much fewer terms in the sum that makes up (64).

Proof of Theorem 9. To assure strong contiguity, we need to establish the convergence of (65). Since the intervals with jumps are negligible, and in view of Jacod and Shiryaev (2003, Theorem IX.7.28 (p. 590-591)), we need to establish that $n^{2}$ is the limit of the predictable quadratic variation of the martingale with end point $L_n$. To calculate the $P_n$-predictable quadratic variation of $L_n$, note that $Cov_P(\hat{\eta}_t, \hat{\eta}_s | Z_{n-1}) = \delta_{t,s} \delta_{t,0} \delta_{s,0} \delta_{t,s} [3]$ (McCullagh, 1987, p. 156). Hence, with $\Delta L_{n,i}$ from (63), we obtain that $\text{Var}(\Delta L_{n,i} | Z_{n-1})$ equals

$$
\Delta t \sum_{t=0}^{n-1} \kappa_i^2 (\tau_{n-1,i}-\tau_{n-1,i})^{2} \delta_{t,s} + \left( \frac{1}{3} \right)^2 \sum_{t,s,r,a,b,c=0} \kappa_i^r \kappa_i^s \kappa_i^t (\tau_{n-1,i}-\tau_{n-1,i})^{2} \delta_{t,a} \delta_{s,b} \delta_{s,c} [3]
$$

which $\kappa_i = \kappa_i (\tau_{n-1,i}-\tau_{n-1,i})$, etc. This shows the result given is the assumption of the theorem.

Proof of Theorem 12. Recall that $P_{n,2}$ is the canonical normal approximation corresponding to the sequence where $A_{n,i} = (\hat{\eta}_i, R_{n,i}, \sigma_{R_{n,i}})$ and $B_{n,i} = \tilde{S}_{n,i}/\sigma_{R_{n,i}} \tilde{V}_{n,i}$. Also let $\hat{A}_{n,i} = (\hat{\eta}_i, \hat{R}_{n,i}, \hat{\sigma}_{R_{n,i}})$ and $\hat{B}_{n,i} = (R_{n,i}/\sigma_{R_{n,i}}, \tilde{S}_{n,i}/\sigma_{R_{n,i}} \tilde{V}_{n,i})$ be the partition from Theorem 10. In both cases, $U_{n,i} = (A_{n,i}/\sigma_{A_{n,i}}, \hat{A}_{n,i}/\sigma_{\hat{A}_{n,i}}, \tilde{V}_{n,i})$, $\hat{B}_{n,i}$, $\hat{A}_{n,i}$ (except for $U_{n,0}$, cf. Definition 7). We observe that under all of $P^n$, $P_{n,1}$ and $P_{n,2}$, $\log f(B_{n,i} | A_{n,i}, U_{n,i-1}, \ldots, U_{n,0}) = \log f(\hat{B}_{n,i} | \hat{A}_{n,i}, U_{n,i-1}, \ldots, U_{n,0}) = \log f(R_{n,i}/\sigma_{R_{n,i}}, A_{n,i}, U_{n,i-1}, \ldots, U_{n,0})$. Thus

$$
\log f_{P_{n,2}}(B_{n,i} | A_{n,i}, U_{n,i-1}, \ldots, U_{n,0}) = \log f_{P_{n,1}}(\hat{B}_{n,i} | \hat{A}_{n,i}, U_{n,i-1}, \ldots, U_{n,0})
$$

The problem therefore reduces to

$$
\log \frac{dP^{*}_{n,2}}{dP_{n,2}} \text{ based on } (B_{n,i}, A_{n,i}) = \log \frac{dP^{*}_{n,1}}{dP_{n,1}} \text{ based on } (\hat{B}_{n,i}, \hat{A}_{n,i}) \text{ as in Theorem 10}
$$

and

$$
\log \frac{dP^{*}_{n,0}}{dP_{n,0}} \text{ where } \frac{dP^{*}_{n,0}}{dP_{n,0}} = \log \frac{dP^{*}_{n,1}}{dP_{n,1}} \text{ based on } (R_{n,i}/\sigma_{R_{n,i}}, \hat{A}_{n,i})
$$

Observe that $P_{n,0}$ is the restriction of $P_{n,1}$ to a smaller sigma-field. $P_{n,0}$ falls under the setup in Section 3.1.2. Because of the independence of the $\hat{\theta}_S$, $P_{n,0}$ is multiplicatively related to the one step contiguous normal target measure studied in Mykland and Zhang (2009, Sections 2.3-2.4). In particular, the cumulants are, in this case, additively related.

The martingale $L_n$ (under $P_{n,1}$) from (64) corresponding to $\log \frac{dP^{*}_{n,1}}{dP_{n,1}}$ is $L_{n,1}$ from Theorem 10. Meanwhile, if $L_{n,0}$ is the martingale (also under $P_{n,1}$) corresponding to $\log \frac{dP^{*}_{n,1}}{dP_{n,0}}$. We obtain in the same way Theorem 10 that

$$
L_{n,0} = \sum_i \Delta t^{1/2} \kappa_i^2 (\tau_{n,i}-\tau_{n,i}) h_0(V_{n,i}) + \frac{1}{3} \Delta t^{1/2} \kappa_i^0 \kappa_i^0 (\tau_{n,i}-\tau_{n,i}) h_{000}(V_{n,i}),
$$

whence $L_{n,2} = L_{n,1} - L_{n,0}$.

The result then follows from the proof of Theorem 10 (in this paper) as well as the proofs of Theorems 1-2 in Mykland and Zhang (2009).
